A WEEKLY JOURNAL OF MEDICAL SCIENCE

VOL. LXXVIII. NEW YORK, SATURDAY, JANUARY 5, 1901. No. 1.

ORIGINAL ARTICLES.

A STUDY OF EIGHTY-ONE CASES OPERATED UPON UNDER ANALGESIA OBTAINED BY SUBARACHNOID SPINAL COCAINIZATION.[1]

BY GEORGE RYERSON FOWLER, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL; SURGEON TO THE METHODIST EPISCOPAL HOSPITAL; SURGEON-IN-CHIEF TO THE BROOKLYN HOSPITAL; SENIOR SURGEON TO THE GERMAN HOSPITAL OF BROOKLYN.

THE extraordinary delay in the application of Corning's discovery to practical surgery no doubt arose from the fact that carefully administered general anesthetics have given such favorable results to the surgeon in the recent past, thanks to the evolution of the professional anesthetist, to such an extent that the possible advantages of the new method were lost sight of and its legitimate place in our science was in danger of being denied to it.

As in many other instances in scientific progress in which only the extreme swinging of the pendulum awakens a general and profitable interest, the profession in this instance is undoubtedly indebted to the enthusiasts who would employ the method in every case in which analgesia by means of spinal cocainization can be produced in the proposed operative area, for a proper appreciation of the indications for and limitations of the new method.

My experience with spinal analgesia embraces eighty-one cases up to the present time. These I have divided into the following classes:

Operations Involving Peritoneum.—Total number of cases, 26. These include 1 case of abdominal section for acute appendicitis; 1 case of abdominal section for chronic appendicitis; 2 cases of vaginal hysterectomy; 6 cases of radical cure of inguinal hernia; 3 cases of abdominal hysterectomy; 1 case of cholecystotomy; 1 case of ectopic gestation; 1 case of inguinal colostomy; 1 case of closure of fecal fistula; 1 case of incision and drainage of mesenteric cyst; 1 case of abdominal section for tuberculous peritonitis; 1 case of Albert-Frank gastrostomy; 1 case of double oophorectomy and salpingectomy, with urachus suspension of the uterus; 1 case of amputation of prolapsed rectum; 1 case of herniotomy for incarcerated and inflamed ventral hernia; 1 case of transperitoneal ligation of the external iliac artery; 1 case of closure of inguinal artificial anus; 1 case of one-sided oophorectomy and salpingectomy.

In five of these cases the analgesia was incomplete. Three of the cases of inguinal hernia were among these, the patients complaining of pain when the distribution of the ilio-inguinal and iliohypogastric nerves was invaded. One was a case of acute appendicitis in which manipulation of the inflamed appendix and surrounding peritoneum gave rise to complaints of pain. In the case of inflamed and incarcerated ventral hernia the patient complained so persistently when the inflamed peritoneal structures were handled that it became necessary to administer a general anesthetic in order to complete the operation. In another of the abdominal section cases, that of ectopic gestation, ruptured three days previously, the patient became frightened at the bustle and stir incident to a sudden renewal of the homorrhage as a large blood-clot was removed, and it became necessary to administer chloroform to quiet her.

In all the cases of abdominal section some embarrassment to the operator occurred at one or more stages of the operation, sometimes delaying the latter for a few minutes. Vigorous peristalsis of short sections of the intestinal canal was noted in all these cases, the contracted areas resembling hard, fibrous cords and presenting sharp borders between the contracted and non-contracted portions, suggesting an imminent intussusception. The patient complained when the hand, previously dipped in an alcoholic solution of sublimate, came in contact with the peritoneum. Perhaps a slightly increased difficulty, as compared with the conditions present under a general anesthetic, was experienced in retracting the edges of the abdominal wound in these cases. Patients did not complain of a moderate Trendelenburg posture, but did express discomfort when an extreme elevated pelvis position was maintained for some time.

Operations in the Pelvic Region not Involving the Peritoneum.—Total number of cases, 34. These include eight cases of hemorrhoids; 12 cases of plastic operation upon the floor of the pelvis and uterine curettage; 1 case of excision of suppurating vulvovaginal gland; 1 case of double orchidectomy; 2 cases of introduction of Harris' segegator; 1 case of urethrocervical fistula; 3 cases of excision of varicocele; 1 case of inguinal adenectomy; 1 case of inguinofemoral adenectomy; 2 cases of Volkmann's operation for radical cure of hydrocele; 1 case of excision of urethral carnucle; 1 case of fistula in ano.

In two of the cases of varicocele the patients complained of pain when the cord was handled, but not to an extent sufficient to render it necessary to employ local anesthesia, by applying cocaine directly to the parts, nor to administer a general anesthetic. In one case of anterior colporrhaphy and perineorrhaphy the sensa-

[1] Read before the Medical Association of Greater New York, December 10, 1900.

tion to pain returned before the completion of the operation, and it became necessary to administer a general anesthetic.

Amputations.—Total number of cases, 5. These include 1 case of amputation at the hip-joint; 1 case of amputation about the middle third of the thigh for elephantiasis; 1 case of amputation at the upper third of the leg for gangrene of the foot and ankle; 2 cases of amputation of a toe for gangrene.

In all of these cases the analgesia was absolute and complete, and the length of time which it lasted was ample for the purposes of the operation.

Operations Upon the Lower Extremity not Included in the Above.—Total number of cases, 13. These include one case of incision of tenosynovitis of the inner hamstring; 3 cases of ligature of both internal saphenous veins for varicose veins; 1 case of arthrotomy of the knee; 1 case of suture of fractured patella; 1 case of excision of tuberculous ulcer of the thigh; 1 case of excision of enchondroma of the ankle-joint; 2 cases of excision of the astragalus; 1 case of excison of varicose ulcer of the leg; 1 case of tenotomy of the tendo-Achillis; 1 case of supramalleolar osteotomy for deformity following Pott's fracture.

In one of these cases, that of tenosynovitis, the patient was a child of ten, in whom but 5 minims of a 2-per-cent. solution was at first injected; after a lapse of fifteen minutes this was found to be insufficient and a second injection of five minims was made, after which analgesia was effected. In a case of ligation of the internal saphenous veins the patient, in spite of the fact that her eyes were bandaged and her ears stuffed with cotton, heard me call for a second knife after an absolutely painless incision of the skin had been made; thereafter she complained of pain upon the slightest touch. The operation of arthrotomy was upon a distended Charcot joint in a case of advanced locomotor ataxia. The analgesia in this case lasted for one hour and twenty minutes above the knees, and for three hours and forty minutes in the parts below the knees. In the case of supramalleolar osteotomy the patient could tell which bone was being chiseled, but at no time complained of pain.

Unclassified Operations.—Total number of cases, 3. These include one case of costal resection for gangrene of the lung and empyema; 1 case of nephrectomy; 1 case of incision of the abdominal wall for suppurating dermoid cyst.

In the case of costal resection the patient's condition was such as to absolutely prohibit the employment of a general anesthetic. While the parts incised before reaching the rib were analgesic the patient complained greatly when the periosteum and intercostal nerve were peeled off of the bone. In the case of nephrectomy the patient declared her absolute disbelief in my statement, made at the completion of the operation, that I had removed her kidney. In the case of incision of the abdominal wall for suppurating dermoid cyst, the latter was situated in the umbilical region. The line of demarcation of analgesia ran across slightly below the point where it was necessary to incise and curette; it was interesting to note that this line persisted at the same level through the whole depth of the operation wound.

The technic of the lumbar puncture sounds simple on description, but is not so in actual practice in all cases. In stout individuals it is difficult to palpate the points of the spinous processes in the lumbar region, and, even in cases in which these are not masked by fat, a nervous patient, particularly when placed in the upright position, will stiffen the deep muscles of the back in such a manner as to render it almost impossible for the operator to confidently fix with the point of his finger the location of the spinous processes. The space between the third and fourth spinous processes is usually the most available, but either the space above or the one below this point may be utilized, if more easily identified.

Usually the cerebrospinal fluid flows readily enough when the needle has indubitably reached the canal, unless the lumen of the needle has become occluded in its passage through the soft parts. Contact with bone at a depth of two inches or less generally indicates, in an average adult, that this is encountered before the canal is reached and demands a change in the direction of the course of the needle; such contact at a greater depth is usually a sign that the needle has traversed the spinal canal, passed through the posterior common ligament and infringed against its anterior wall. A sensation of suddenly passing through a tense membrane and entering a free cavity is sometimes sensibly appreciated by the operator as the needle perforates the interspinous ligament, which, in the lumbar region is comparatively well developed. The use of a double needle will permit the operator to eliminate the accident of occlusion of the lumen of the instrument in cases in which he has reason to believe that the canal has been reached and yet no fluid flows. Removal of the inner needle under these circumstances will permit clearing without giving rise to the necessity for a second puncture. When a double needle is employed the inner or finer needle, projected beyond the outer for a half inch, will give the advantage of entering the spinal canal with a fine, rather than a coarse needle, the outer needle reinforcing the inner one, which, if made only just large enough for the cerebrospinal fluid to flow through and used alone would be too fragile for safety. Aspiration, either with the attached syringe or a special suction bulb, will enable the operator to obtain the cerebrospinal fluid promptly, as well as to control the amount removed and preserve the fluid for examination or use as a solvent for the cocaine to be injected.

I usually allow a full minute for the injection, thus giving time for the solution to mingle evenly with the cerebrospinal fluid. The solution should be freshly made with sterilized water, and boiled for one minute before using. It is better to dissolve a given quantity in either ten or twenty minims of water. I have noticed no difference in the disagreeable symptoms whether a quarter or half a grain is used. For a short operation I use the former, and for a longer operation the latter. A concentrated solution of a definite quantity is no more likely to produce disagreeable symptoms than the same dose in a dilute solution, and its effect will last longer.

The position in which the patient is placed during the injection seems to affect but very little the result so far as the analgesia is concerned, although I have thought that the Sims' position rendered the patient more comfortable and tended to relax the back muscles.

Analgesia is present in the soles of the feet in from one to five minutes, and extends to the umbilicus in from five to fifteen minutes. In none of my cases did it fail to reach the umbilicus when it was effective at all; in two cases it reached to the vertex. In no case did the analgesia subside in the regions below the umbilicus under twenty-seven minutes (one case); in all the rest it lasted more than forty minutes save in one, in which it subsided in thirty-one minutes. If from one-fourth to three-eighths of a grain dissolved in ten minims of sterilized water be used, analgesia to and including the perineum may usually be depended upon for a forty-five-minute operation.

Probably the extent of the analgesia, as well as its duration, depends somewhat upon the amount of cerebrospinal fluid present in the individual case. Progressive dilution of the cocaine solution from the point of introduction lessens the effect of the drug upon the nerve structures with which it comes in contact, until, finally, if the amount of cerebrospinal fluid be large in the given case, this is practically nil at points high up in the spinal canal. The circulation of the cerebrospinal fluid comparatively free from cocaine through the lymph-spaces in the nerve-structure, washes out the cocaine solution carried to these by the cerebrospinal fluid when the injection is first made, until, finally, the cocaine is so diluted in the general bulk of the cerebrospinal fluid as to be useless for the purposes of analgesia.

Failure to induce analgesia may be said in general terms to be due to failure to inject the solution into the spinal canal, providing the solution is trustworthy. That fluid other than that from the spinal canal may be procured by aspiration, I know from experience. I have known operators to inject the cocaine solution when no fluid has been procured. The result has been only what could have been expected, namely, failure to produce analgesia. In one of Laplace's cases[1] the failure was attributed by the operator to probable syphilitic disease of the meningeal sac at that point.

From the very first case in which I used the method (September 8, 1900) I have employed a preliminary injection of cocaine at the seat of proposed puncture in order to avoid possible involuntary movements on the part of the patient, when the latter was made, and consequent risk of breaking the needle in the deeper parts. I have also made a slight puncture with the point of a scapel for the purpose of minimizing the dangers of conveying infection within the spinal canal from the skin itself.

In the majority of my cases one or more of the disagreeable features, so well known to be incidental to the method, have been present, namely, vertigo, nausea, vomiting, headache, chills, rise of temperature and increased pulse-rate, pallor, cold sweat, and involuntary defectation and urination upon the operating table. In some cases a slight cough has preceded the nausea. That all of these are due to the drug *per se* I cannot admit in the face of the fact that they have occurred to an equal extent whether large or small doses were used, as well as in cases in which antipyrin or chloretone was alone administered. Not only this, but in one case vertigo, pallor, cold sweat, sighing respiration, increased pulse-rate with lessened force, cough, nausea and vomiting all took place when the puncture was made and a drop or two of cerebrospinal fluid withdrawn, and before any injection whatever had been made.

Vertigo has been complained of by the patient while upon the table in three cases only, including the one just cited. Nausea came on in from five to ten minutes in about half of the cases, and actual vomiting in about two-thirds of these. In the majority of instances in which vomiting took place it subsided in less than two minutes, generally when the stomach was emptied of the fluid taken or gastric secretion present. Exceptionally dry retching was troublesome for a few seconds at a time later on during the operation. Headache occurred in about two-thirds of the cases after the patient had been returned to the ward, and at periods varying from one to six hours. Its duration and severity varied greatly from a transient frontal distress to severe general cephalalgia lasting for from twenty-four to forty-eight hours. In the mild cases it disappeared spontaneously, while the severe cases resisted all the usual remedies. Rise of temperature has been noted in all the cases. This likewise has presented all graduations, from an evanescent elevation to a decided and comparatively prolonged febrile disturbance. In one case the temperature reached 106.8° F. in less than four hours. Pronounced chills were observed in only four cases. Increased pulse-rate alone has always seemed to me to be an incident of the nervousness of the patient, rather than the immediate effect of the injection, for the reason

[1] Phila. Med. Journal, Nov. 3, 1900.

that in the majority of cases it has been less when the patients left the operating-table than when they were placed upon it and just before the injection was made. These features frequently corresponded, upon the patient's return to the ward, to the condition present at the last observation before being taken to the operating-room. There has seemed to me to be some relation between the nausea and vomiting and the force of the circulation. When the former has been most pronounced the heart's action has been the feeblest. In recent cases I have attempted to guard the heart during this, the most trying portion of the seance, by a preliminary injection of one-tenth of a grain of strychnine, and with some success.

Involuntary defecation took place in less than one-eighth of the cases. The patient was conscious of its occurrence in four out of the five cases. In all but one it occurred during an act of vomiting. In one case the patient had a bowel movement and urinated involuntarily while lying perfectly quiet, and was not conscious of the occurrence of either. In all of the cases in which the sphincter ani relaxed beyond the patients' control the customary preparation, including a purge the night before, had been made. In one, a case of hemorrhoids, the patient had no preparation whatever. No nausea nor vomiting took place, although he had eaten a hearty meal a few hours before. I do not look upon this observation as of value, however, until confirmed by further experience.

Pallor, cold sweat and sighing respirations have only occurred when nausea, vomiting and diminished circulatory force have been present, and have disappeared with these latter. This entire aggregation of symptoms, save the nausea and vomiting, have been decidedly lessened since I began the preliminary use of the tenth-grain dose of strychnine hypodermically administered. Inasmuch as the dangers from the method probably relate to circulatory failure, whether this be from the effects of the drug itself, or the result of the disturbance of the nerve centers by increase or decrease of the intraspinal pressure or the presence of fluid foreign to the normal environment, I deem it important that provision be made against this contingency by the preliminary use of a full and sufficient dose of strychnine.

Beyond mere rumor, I have no information as to deaths occurring after and attributed to the use of spinal cocainization. In a recent discussion upon this subject it was stated that deaths had occurred, but no authority was given. These rumors came to me while in Paris last summer, but could not be traced to a trustworthy source. Severneau of Bucharest, in his remarks before the Thirteenth International Medical Congress, although he alluded to the general weakness observed in his group of cases, numbering seventy, did not speak of any deaths, although he took a conservative ground in regard to the method. Tuffier, whose case in which death occurred on the day of the operation has been referred to by those who think adversely of the method, detailed the post-mortem findings, which included both cardiac and pulmonary lesions, in this case and distinctly stated that, in his opinion, the injection of cocaine had nothing to do with the death. Pitesci of Bucharest, with a record of one hundred and twenty-five cases, the same number operated upon by Tuffier under spinal cocainization, reported no deaths, although he stated that two deaths have occurred from its use in Roumania[1].

My own cases are not selected ones. Cardiac, renal and pulmonary lesions have been disregarded for the sake of giving the method an absolutely fair trial. Many of the patients had heart murmers, not a few were the subjects of degenerative kidney disease, and one, at least, suffered from the gravest of all pulmonary lesions, namely, gangrene of the lung, from which he died a week later. One patient had actual suppression of urine, which was unknown to me at the time of operation. The patient upon whom amputation at the hip-joint was done was an exceedingly weak and feeble old woman of sixty-eight. The patient upon whom Albert-Frank's gastrostomy was done was a half-starved subject with occlusive carcinoma of the esophagus and esophagotracheal fistula. The case of tuberculous peritonitis was in a patient far advanced in the disease and greatly emaciated, and in whom an incision from the ensiform cartilage to the symphysis pubis was made. It was necessary to extend the incision upward in order to reach a gastric ulcer which I had suspected to exist, and which I saw perforate through a small and distinctly circumscribed gangrenous patch upon the anterior stomach-wall just as the edges of the incision in the abdominal wall were retracted. The case of tuberculous ulceration of the thigh was that of an exceedingly feeble old man of sixty-three, upon whom double castration for tuberculous testicle had been previously performed. The amputation of the leg was done on an old and feeble woman of sixty-nine, with arterial sclerosis, gangrene of the foot and ankle, and the dry tongue and low mental condition of septicemia. Another case was one of advanced degenerative disease of the spinal cord itself. The ectopic gestation was in a woman who had lost a large amount of blood. The nephrectomy patient was thoroughly septic and died ten days afterwards of general exhaustion and pyemia, the autopsy showing old foci of infection in the remaining kidney. The inguinal colostomy was done on an extremely feeble old man with advanced cancer of the rectum, with albumin and hyalin and granular casts in the urine. Time,

[1]My impressions of these matters, gathered on the spot and at the time the subject was under discussion at the Congress, are confirmed by the correspondent of the *British Medical Journal* whose information was derived from the official records. (See *British Medical Journal*, Aug. 25, 1900.)

however, will not allow me to refer to these at greater length. Suffice it to say, however, that these patients, in whom a general anesthetic was unsuitable in the judgment of any surgeon, showed, as a rule, less pronouncedly alarming effects from the spinal cocainization than many of the younger and far more vigorous subjects in my list.

I have endeavored to employ antipyrin alone, following the suggestions of Nicoletti of Naples, who reported at the Paris Congress some successful experiments with this drug upon dogs. In the first case I could not be sure, owing to the fact that the patient was a stoical Italian woman who spoke no English, of its analgesic effects. In a second case this drug failed entirely. In another case I injected 15 minims of an eight-per-cent. solution of chloretone, it being alleged that this agent is an analgesic, which, experimentally, had been shown to exist unchanged in the cord after injection. This also failed to produce analgesia. A combination of antipyrin and cocaine seemed to give somewhat better results proportionate to the amount of cocaine employed, so far as the analgesia was concerned. I am not prepared to state at this time just what advantages may be derived from endeavoring to lessen the amount of cocaine by using a mixture of this with other agents. Up to this time the after-effects of these mixtures, as well as those following the injection of fluids other than cocaine, have not been less than in cases in which cocaine alone was used.

In closing I wish to state that, in spite of my favorable experiences with spinal cocainization, I hold to the proposition that the ideal anesthetic agent is one which, with absolute safety, will render the patient entirely oblivious, not only to the pain of the operative procedure, but to each and all of its disagreeable features as well, including knowledge of the surroundings, the fear and prolonged dread of a fatal result during the operation itself, this being possibly enhanced in the case of a patient fully conscious, by the thought that his life hangs upon the point of the surgeon's knife, and that the slightest movement involves the greatest danger. These, together with the disagreeable incident of vomiting, to say nothing of the disgusting occurrence of involuntary urination and defecation while upon the operating-table, should be eliminated from the conscious environment of the patient, whenever possible, with absolute safety. These propositions are self-evident in all cases, but are particularly true in surgery. In obstetric practice, on the contrary, even in the case of a primipara, the patient is more or less prepared, by long looking-forward to the important and crowning event of her maternal instinct, for not only painful, but disagreeable and what under any circumstances cannot but be disgusting features of that event. Not so in surgical practice, in which the announcement of the necessity for an operation is a shock in itself, from which the patient scarcely has time to recover before being called upon to undergo the ordeal itself. While, in certain exceptional instances, the patient will dread the enforced loss of consciousness, the greatest fear on the part of the latter arises from the supposed dangers incident to the anesthetic agent. Take away this fear and the positive promise of an absolutely harmless *nepenthe* will far outweigh the suggestion of an experimental analgesia.

I am impelled to make these remarks by a consideration of the matter from the standpoint of the patient's own feelings, a point of view which cannot be ignored. That the ideal anesthetic has not yet been discovered, is unhappily only too true; that this much-to-be-hoped-for event will come along the line of thought suggested by general rather than local anesthesia or simple analgesia, and through an elimination of all the disagreeable features of the surroundings, rather than a more or less transient suspension of the pain-transmitting function of the nerves involved in the operation, I am persuaded.

At the present time we may only say that Corning's method has an undoubted sphere of usefulness in surgery. The indications for and limitations of, as well as whatever danger may attend its employment can only be determined by further trial and careful study of a large number of cases.

THE HISTORY, AIM AND PURPOSE OF THE MEDICAL SOCIETIES OF THE STATE AND COUNTIES OF NEW YORK.[1]

By FRANK VAN FLEET, M.D.,

OF NEW YORK;

CHAIRMAN OF THE BOARD OF CENSORS OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK; CHAIRMAN OF THE COMMITTEE ON LEGISLATION OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

THERE is in the thought and feeling of every true American, a sense of reverence which steals over him, permeating and thrilling every fiber of his body, when he reads and thinks of the history of his country, and pictures to himself, in all grandeur and majesty, the nobleness of character and the self-sacrificing labor of the people who fought and died in the creation of this great Republic.

There should arise in the thought of every member of the Medical Society of the County of New York a feeling second only to the reverence and admiration he feels for the United States of America and its constitution, when he remembers the history of his Society and all it stands for. The Constitution of the United States stands for the protection of the rights of man, while the constitutions of the Medical Societies of the Counties of this State stand for the protection of the public health. The Government of the country recognizes no creed, and the Medical Societies of the

[1]Read before the Medical Society of the County of New York, November 26, 1900.

Counties of the State of New York but follow this example when they recognize no creed.

The Medical Society of the County of New York is only one of many such societies, all of which are parts of the Medical Society of the State of New York. This system of medical societies was created by Act of Legislature in 1806, and is no new and untried experiment; its organization dates from the early years of the State government itself. When we consider that in 1806 the Constitution of the United States was in its nineteenth year, and that the government of the State of New York was then only in its twenty-ninth year, we begin to feel that in our Society it is not a child that we have to consider. This organization has lived through many trials and vicissitudes, but year after year it has held its sessions, fulfilling its proper functions, until now, in the ninety-fifth year of its existence, it stands in relation to the State just where it stood in 1807 under the presidency of Dr. William McClelland; where it has stood ever since, and where we sincerely hope and trust it will stand as long as the State government exists, as the representative of the regular medical profession of the State of New York and the proper guardian of the public health. The Medical Society of the County of New York is part and parcel of the Medical Society of the State of New York, and what we say of one applies to the other, and to the society of every county in the State.

This organization is a scientific body; that is, it is made up of members who are versed in the science of medicine. One of the functions of this organization is the dissemination and propagation of the knowledge and the science of medicine. This, however, is not the principle motive for its creation and the perpetuation of its existence. This Society was organized by the Legislature under Chapter 138 of the Laws of 1806, for the purpose of "regulating the practice of physic and surgery in this State," and, while there was a period of about thirty years when this Society had little or nothing to do with the regulating of the practice of physic and surgery, because there was no regulating done, whenever there has been any effort made to regulate this practice it has been through the good offices of this Society, and the Legislature has delegated to this Society the burden of the enforcement of the State's medical laws

At the time of the American Revolution there were about thirty five hundred practitioners of medicine in the American Colonies, of whom only four hundred were educated physicians. Indeed, prior to 1768 there were no colleges in the American Colonies where the degree of doctor in medicine could be obtained. In that year (1768) the first degrees in medicine were conferred on ten men by the Medical College of Philadelphia. Between the years 1768 and 1776, when war suspended the operations of the Philadelphia Medical College and King's Medical College—now the Medical Department of Columbia University—fifty-one medical degrees had been conferred. All other practitioners of medicine either obtained their degrees abroad or practised without degrees.

Virginia as early as 1739 made laws regulating the fees of practitioners of medicine, and in 1760 New York enacted a law compelling physicians to pass an examination in physic and surgery, which, inasmuch as it was conducted by the Judges of the Supreme Court, the Attorney General and the Mayor, was probably not very rigid. The American Revolution coming in 1776, and the country being in a more or less disturbed state after the cessation of hostilities, it is doubtful if any adequate measures were adopted to regulate the practice of medicine until 1806, when the Medical Society of the State of New York and its county branches were established. This law creating medical societies marks an epoch in the history of medicine. It is entitled "An Act to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this State," and gave to the societies so incorporated the right to examine students in medicine and grant licenses, as well as to prescribe the methods of practice.

We see from this how great the esteem in which the medical profession was held by the public. The Legislature, recognizing the necessity of regulating the practice of medicine in order to properly protect the health of the community, created these medical bodies, one in each county, with one member from each county society to make up a central body or head, not for the purpose of protecting practitioners of medicine, not for the promotion of medical science, not for the purpose of perpetuating good fellowship, nor for the creation of a code of ethics. The sole object of this enactment was, as stated in the title of the Act, "for the purpose of regulating the practice of physic and surgery," in order that the citizens of the State might be protected from incompetent practitioners of physic and surgery. The State by this Act created a special department which became an integral part of the machinery of the State, and to this department was given authority to examine students and grant licenses to practise medicine, and to prescribe the method of practice. Without a license so obtained no physician could legally practise medicine. This relation continued to exist between the State and the various County Societies for thirty-eight years with slight changes. The law was re-enacted in 1813, and in 1814 the creation of societies in counties set apart since the Act of 1806 was legalized.

In 1818 a law was passed allowing certain county societies to change the date of meeting when it occurred on the same day on which the Court of Common Pleas met. It authorized medical colleges to send each a delegate to the State society, and it directed every practitioner of medicine in the State to report himself to and connect himself with the medical society of the county in which he resided. In 1810 a law was enacted authorizing each county medical society to tax each physician in the county a sum not exceeding one dollar a

year, for legitimate expenses. In 1830 the revised statutes re-enacted all these previous Acts. In 1837 and 1839 the University of the City of New York and the Albany Medical College were authorized to send delegates to the State society. So matters continued, the Legislature yearly strengthening the power of the State society, until in 1844 a law was enacted (Chapter 274, Laws of 1844) removing all the restrictions hitherto existing and allowing any person, regardless of qualifications, to practise medicine. This radical change was brought about by the spirit of intolerance which had grown up in the medical profession, fostered no doubt by the provisions of the Act of 1806, which directed county societies to prescribe the methods of practice which should be the only legal methods. It seems strange, indeed incomprehensible, that at so late a period as 1844 there should be found anywhere in liberty-loving America, in its largest State, and above all in a profession which is now at least a liberal one, a feeling so intolerant of the rights of others that, because a colleague differed in opinion as to methods of practice, the entire profession should not only ostracize him, but prevent him practising medicine, robbing him of his social standing, and preventing him following the only occupation he was, perhaps, capable of following.

We wonder at the narrow bigotry and benighted ignorance of the New England Puritan in 1692, when in three months twenty-three persons were hanged at Salem as witches, or because they were "possessed of the devil." We wonder at the intolerance of a hundred years later when men were disenfranchised because of their religious beliefs, but we find this same spirit of intolerance dominating the medical profession in 1842, when a member of the Orange County Medical Society was expelled for practising contrary to the prescribed method, and again in 1867 when the Westchester County Society expelled a member for buying sugar of milk at a homeopathic pharmacy. Many of us, no doubt, think we have happily left all these narrow feelings far behind us, and that there exists now no such intolerance as was possessed by the generation which preceded the one in which we live, but those of us who are most familiar with the political events which are occurring in medical affairs know that this spirit still exists, and that there is an association in the State of New York, with its home in the City of New York, organized for no other purpose than to keep alive this intolerant and un-American spirit, and which has prevented the Medical Society of the State of New York accomplishing many needed reforms in medical affairs.

Every society or organization the years of existence of which are counted in decades, has been party to transactions which appear to its members of succeeding generations as reprehensible, and the Medical Society of the State of New York is no exception to this rule, but, whatever may have been the errors of the past, the Medical Society of the State of New York and its county branches present to the world the proud distinction of being the only medical body of its kind in the United States in which freedom of thought and action is tolerated, the members of which are restricted by no narrow bonds, and in which the only requirements of membership are liberality and broad-mindedness.

Prior to 1844 there was but one legal school of medicine in this State; indeed, under the law there could be but one, and that the one provided by the State Society and its county branches. There were then none of the refinements of medication which we possess to-day; the recognized methods were blood-letting, blisters, cathartics and emetics, and it was heresy to advocate any other methods. People who fell victims to disease died often because of the heroic measures employed to counteract the maladies which afflicted them. Indeed, many physicians began to feel that more patients would recover if Nature was left unaided to fight the disease. Few, however, had the temerity to voice these sentiments, and the few that did suffered ostracism because of their expressed views. In England Sir John Forbes incurred the displeasure and contempt of his fellow practitioners by expressing his belief that no treatment at all was better than the treatment then in vogue. This was the condition of affairs in the early part of the nineteenth century, and it is little wonder that when Hahnemann began to teach his doctrines he soon found many followers. Any method was better than the methods then practised. Homeopathy came at this time as a welcome variation, which would have been tried, tested and discarded years before it was had it not been for the intolerance of the regular profession. There would have been no homeopathic school of medicine, there would have been no code of ethics, and possibly we would not have had our present medical laws. However, those who wanted to and did practise homeopathy were expelled from their county societies for so doing, and as such expulsion under the law was equivalent to being debarred from practising medicine, they united and secured the repeal of the medical laws as a matter of self-protection.

For thirty years the State of New York had no medical laws for the protection of the public health. There was a section of the law which repealed the former law, providing that a practitioner of medicine was liable for damages for maltreatment, but there was no law requiring either education or training on the part of these practitioners.

This deplorable condition of affairs, which was not confined to New York State, led to the meeting of the regular profession from all over the country in New York City in 1846, and the forming of a voluntary body for the improvement of the practice of medicine and for self-protection. This organization is now known as the American Medical Association and its organization is antedated by that of the American Institute of Homeopathy, which was created in 1844, both being created for the same purpose. Opposition between

the adherents of these two bodies continued with increasing bitterness, and in the State of New York prevented the enactment of medical laws which would properly protect the entire community.

Various laws were enacted, it is true, but the proper protection of the public health, by the enactment of a law along the lines laid down by the Medical Society of the State of New York in a resolution passed by that body in 1839, advocating the separating, as far as possible, of teaching and licensing bodies, was rendered impossible by the antagonism existing between the various branches of the medical profession representing the different schools of medicine. The regular school of medicine refused to recognize the homeopathic and eclectic schools, refusing to meet the members of these latter schools in consultation, until in 1882 the Medical Society of the State of New York by a substantial majority abolished the code of ethics, thereby allowing its members the privilege of meeting any legal practitioner of medicine in consultation. The far-reaching influence of this action on the part of the State society has been greater, perhaps, than many of its advocates at the time contemplated, although there may have been those among them who realized what the result would be.

The first effect of this action was to bring the warring elements closer together, and as they began to see how similar they were in many particulars and how their constant strife prevented the enactment of laws which would benefit themselves and the public at large their interests began to appear identical, and as the result the present medical laws were enacted.

These laws stand to-day as a monument to the Medical Society of the State of New York and its county branches. Being the oldest and most representative medical body in the State, the State society has always taken the initiative in matters of this kind and through its efforts, seconded by the representatives of the homeopathic and eclectic branches of the medical profession, there has been placed on the statutes books a law governing the practice of medicine which has been and is a model from which many other States have drawn inspiration, and which serves as a guide which other States have been glad to follow. To gain the right to practise medicine in the State of New York to-day means something. It means that the man who has gained this right has demonstrated to an impartial board that knew him only by number, his ability to practise medicine, and the certificate of proficiency granted by the State, as the result of this examination, stamps the successful candidate as the peer of any practitioner of medicine in the world. It makes no difference who the candidate is, from how many colleges and universities he may have received degrees and diplomas. He may possess a name which is known the world around, yet if he desires to practise medicine in the State of New York he must take his stand with the newest arrival and demonstrate his ability to the State Board. This examination is alike for all, regular, homeopathic and eclectic.

The opponents to this law claimed, and there are not wanting those who still make this claim, that the effect of this law would be to diminish the number of practitioners in this State, and that it was intended solely for the protection of those who already had the right to practise. A glance at the figures of the State Board of Medical Examiners will prove that this is not the case, as there has been a steady increase in the number admitted year after year. The number admitted in 1899 was 671, in 1895, 482.

The result of this law has been the raising of the standard of requirements in this State, and an improvement in the teaching of undergraduate schools, which has not only been beneficial to our own State, but has been an incentive to other States. There are imperfections in this law which prevent its proper inforcement. These imperfections should be remedied and would be were it not for the enemies with which the State and County Societies have to contend. There was a time when the enemies we had were only those outside our ranks; to-day the only enemy we have outside our ranks is the army of illegal practitioners, and these we could easily overcome; indeed, we could, in a short time drive this enemy out of the State of New York were it not for the enemy within our own gates.

The three branches of the medical profession recognized by the State, *i. e.,* the regular, homeopathic, and the eclectic, have worked hand in hand, and harmoniously, in securing the enactment of laws for the proper protection of the public health, and doubtless will continue to do so; there is, however, an organization which has done, and is doing, its utmost to overthrow the Medical Society of the State of New York and its county branches, and the Committee on Legislation of the State society is compelled to be constantly on the watch to frustrate the efforts of this organization. We refer to the New York State Medical Association and its county branches. This association represents a principle which is antagonistic to the medical laws of the State of New York, as well as to the spirit of the constitutions of this State and the United States. This principle was formerly upheld by the Medical Society of the State, and it resulted, as we have said, in the overthrow of the medical laws of the State in 1844.

When the State society refused to be governed by the Code of Ethics of the American Medical Association, it abolished also this principle, and made possible the enactment of the present medical laws.

The State Medical Association has representation in the American Medical Association, which latter is not a chartered body, but a purely voluntary organization, and which, as such, should not presume to dictate to the State Medical Society, which is a chartered body, and a part of the machinery of the State of New York. The State society has no representation in the American Med-

ical Sociation, because it refuses to be governed by the Code of Ethics of the latter organization.

Now, why does the State society refuse to be governed by the Code of Ethics of the American Medical Association, which, on the surface, seems harmless enough? Because the Code of Ethics of the American Medical Association upholds a principle which is un-American, is contrary to the teachings of the Constitution of the United States, and is contrary to the dictates of humanity. The Code of Ethics has much to say about the dictates of humanity, but it ostracizes from the pale of professional intercourse and consultation any person who believes contrary to what the association thinks he ought to believe, and this is contrary to the spirit of the Constitution of the United States, which gives to every man, without penalty, the right to believe as his conscience or intellect directs.

No matter how much this code may dwell on the dictates of humanity, and the duty of the physician to his patient and to the community, when it says, "No one can be considered a fit associate in consultation whose practice is based on an exclusive dogma," it denies to humanity the very boon the regular practitioners claim to be able to bestow, namely, intelligent treatment. Medicine is not a commercial calling, nor is it so narrow that its followers should allow themselves to be swayed by whims and individual prejudices; we have always felt that the physician who refuses to give the benefit of his advice as a consultant because the attending physician may be one with whom he could not possibly agree, fails to appreciate the dignity and responsibility of his calling. Many physicians deny the benefit and need of consultations, when the consultants are members of the regular school, but surely no regular physician should hesitate to give the benefit of his knowledge to the patient who is being treated by one whose practice is based on an exclusive dogma.

True, those who uphold this Code do not refuse to consult with these so-called irregular practitioners; at least, this statement was made by the officers of the New York State Medical Association before the Senate Judiciary Committee at a hearing during the last session of the Legislature. Why, then, do they persist in demanding that we subscribe to this Code, which no one believes in, and which the officers and members of their Associations publicly discredit?

The first organized effort of the New York State Medical Association to dispute the right of the Society to represent the regular profession in this State was made in 1807, when the Legislature was petitioned to grant the Association equal representation with the Society in the State Board of Medical Examiners. This the Legislature refused to grant. The second effort was made during the last session of the Legislature, when the Association requested a special charter authorizing it to assist in the enforcement of the medical laws. The Legislature saw no objection to the Association having a charter and accordingly granted it, but refused to grant it the right to assist in the enforcement of the medical laws. In all its efforts before the Legislature the Association has failed to secure equal recognition with the Society, and now it has resorted to the courts.

New York City has on its hands a lawsuit which, if the legal authorities did not think was unjust, the city would have settled before this. This lawsuit is known as the New York County Medical Association vs. the City of New York, and, while it is nominally brought against the city, it is really the final effort of the County Association to compel the Medical Society of the County of New York to divide with the Association the work of enforcing the medical laws.

The present medical laws begin by recognizing three medical bodies: the Medical Society of the State of New York, the Homeopathic Medical Society of the State of New York, and the Eclectic Medical Society of the State of New York, and to each of these societies it gives the privilege of nominating members of the State Board of Medical Examiners. The law is very explicit in naming these three societies, which recognition undoubtedly constitutes these societies, in the eye of the law, the representatives of the medical profession. The State recognizes and controls the medical profession through this law and through these Societies, and must therefore consider these three Societies as the profession's representatives. The Board of Regents of the University of the State of New York appoints the Board of Medical Examiners from the nominees presented by these three Societies, and if either of the three Societies neglects to nominate candidates for the positions of State Medical Examiners, the Regents may appoint from members in good standing of such Society without restriction. The Regents may not appoint from the members of any other association of medical men or from any academy of medicine, but may appoint from the membership of the three Societies mentioned in the law. The section of this law providing for the penalty for violation of the law and the collection of fines gives to any incorporated medical society of the State or to any county society entitled to representation in a State society, the right to receive the fines collected as the result of complaints made by such Society. This the New York County Medical Association claims is broad enough to include it, and, acting on this assumption, made a complaint against an illegal practitioner, which led to a conviction, and then claimed the fine. The Comptroller of the City of New York refused to pay the fine over to the Association, claiming that the county society referred to in the section of the law authorizing the payment of the fines to societies making complaints was the organization having representation in one of the three State medical societies named in a preceding section of the law. The Association then requested an interpretation of the law from the Attorney-General, who gave it as his opinion that the word "society," as used in this section of the law, was broad enough to include the

Association. The Comptroller, however, refused to be guided by this interpretation. He sought the advice of the Corporation Counsel, who requested a brief from the counsel of the Medical Society of the County of New York. Our counsel submitted a very comprehensive and exhaustive brief, as the result of which the Corporation Counsel decided that there was grave doubt that the Association was entitled, under the law, to receive fines for this purpose.

The Association then asked the Legislature to grant it the right to assist in the enforcement of the medical law, which request the Legislature, as we before stated, refused to grant. The Association then brought suit against the city to compel the payment of the fine in question, and Judge McAdam in the Supreme Court ruled that the Association was entitled to the fine. Under this decision the city had authority to pay the fine into the treasury of the county association, but neither the Comptroller nor the Corporation Counsel were satisfied with this decision, and the City of New York has appealed from the decision of Judge McAdam, which appeal will be argued before the Appellate Division of the Court in the near future, when we have every reason to hope and believe that the decision will be reversed.

According to the wording of the decision, the learned judge was evidently influenced by the fact that the Association has representation in the American Medical Association, and was of the opinion that the law would be better enforced if more than one medical body was on the lookout for violators. It does not require a legal mind to determine that neither of these points are at issue in this suit; the question to be determined—and which is simply a question of interpretation—is, Does the law, as it stands, give the Association the right, with the Society, to receive fines imposed for violations of the medical laws?

We must leave the determination of this question to the courts, but it is of interest to us, as physicians, to settle these two questions, namely, do we desire representation in the American Medical Association, and, will the work of enforcing the medical laws be better accomplished if the work is done conjointly by the Medical Society of the County of New York and the New York County Medical Association?

Let us consider these two questions. Is it desirable that the Medical Society of the State of New York should have, with the county branches, representation in the American Medical Association? The American Medical Association was organized as the result of a convention held in New York City in 1846, so that it can be truly said to have had its birth in this city. It has grown to be a National body, but is purely voluntary in its character, and not, like the Medical Society of the State of New York, an integral part of any State government. This American Association is an incorporated body, but has no fixed place of meeting. It meets yearly at a time and place agreed upon and holds meetings where scientific subjects are discussed. It fulfils an important function which no one ought ever to try to underestimate; indeed, no one ever does.

The Medical Society of the State of New York has not the migratory habit of the American Association, but meets yearly at a definite time in Albany, the State capital, during the time the State Legislature is in session. It, too, transacts a scientific business, but in addition to this it occupies the position as the State's regulator of the practice of medicine. It has done much to uplift the medical profession and protect the public health. It certainly should be represented in every National medical body, and should and would be represented in the American Medical Association were it not for the Code of Ethics of the latter body, which our State society refuses to endorse, and which even the members of the Association admit that nobody lives up to. We feel that we cannot openly subscribe to a Code which privately we must violate. When the time comes—as we hope it soon will—when the American Medical Association agrees to allow each State to regulate its own ethics and invites the Medical Society of the State of New York to send delegates to the National body, then the unhappy breach which now shuts out the representative medical body of the largest State in the Union will be closed, and the Medical Society of the State of New York will gladly send its delegates to the American Medical Association.

Will the medical laws of the State of New York be better enforced in the City of New York if the Medical Society of the County of New York and the New York County Medical Association each employ counsel, secure evidence, and receive fines?

The Legislature of the State of New York expressed its disapproval of this dual relation when it enacted the present medical laws, and repeated its disapproval during the session of 1900, when it refused to grant the Association the right to assist in the enforcement of the general medical laws of the State. The District Attorney of the County of New York, the judges before whom most of the suits for violation of these laws are tried, and the various departments of the city government whose officers are familiar with the work of preparing and trying these suits, are on record as being opposed to dividing the responsibility between the Society and the Association. For ourselves we can only say that we believe such a division will result in confusion; will increase the cost and diminish the efficiency of the work of prosecuting violators of the medical laws, which work has been carried on by the Medical Society of the County of New York for several years.

It is, perhaps, unfortunate that any organization of medical men should be burdened with the task of enforcing the medical laws, and have the privilege of receiving the fines imposed. Such an arrangement immediately gives rise to the belief in the minds of misinformed people that the prosecutions so conducted are in the nature of persecu-

tions. When the Medical Society of the County of New York began the work of prosecuting violators, this erroneous belief was one of the chief obstacles which had to be met and overcome. Not only did the general public entertain this belief, but juries, and even judges were inclined to the same belief. Indeed, our counsel was frequently asked in court if his fee in the case depended on a conviction. It seemed impossible to believe that any society would conduct prosecutions of violators of laws unless there was a motive of personal gain back of it all. Passing years have eradicated this belief in the case of judges and juries at least, and even the general public is coming to look upon the work done by this Society in its true light. Complaints which are made to the courts, to the Health Department and to the District Attorney's office, by private individuals, of violations of the medical laws, are now referred by these judicial bodies to the counsel of our Society for investigation. Years of experience have enabled us to build up a system which renders the detection of illegal practitioners of medicine easier every year, and convictions are moderately certain. To divide the responsibility now will certainly cause confusion and interfere with the work which is being done. Even now complaint is made that the law is not properly enforced, and the complaint is, to a certain extent, just. The law is, however, being more rigidly enforced with succeeding years, and before long the time will arrive when the public will be educated to see the necessity of still more rigid enforcement, and the weak points which now exist in the law and which add to the difficulty of enforcement, will be remedied so that the public health may be properly protected.

A division of the work of enforcing the law will greatly increase the expense. The Medical Society of the County of New York employs a counsel, whose work consists in securing evidence and conducting prosecutions of illegal practitioners of medicine. For this service the Society pays a yearly salary of $1,000, and in addition to this the Society expends over $1,800 yearly in securing evidence. This expense of nearly $3,000 a year is offset, in a measure, by the fines received. In the past five years, however, not including the year 1900, this Society has spent in the work of protecting the community from incompetent practitioners of medicine over $13,000, and received in fines between $7,000 and $8,000, leaving a deficiency of over $5,000, which had been paid out of the treasury of the Society. The division of this work will necessitate a doubling of the expense, will create a rivalry in the work of securing evidence which will certainly bring discredit on both the Society and the Association. It may seem to some that a division of this work will distribute the burden of expense, but as the membership of both the Society and the Association is made up largely of the same individuals, *i.e.*, the members of the Association are, in most cases, members also of the Society, it will be seen that the expense of conducting these prosecutions for the Association will fall on the medical practitioners who are already paying for the same work in the Society.

The more familiar one becomes with the subject of medical politics in the City and State of New York, the more absurd does the peculiar condition which exists appear. We have two county and two State medical bodies, diametrically opposed in principle, yet the membership in both made up of nearly the same people. Probably very few members of the medical profession have given much thought to this subject. They will be surprised when we tell them that over 67 per cent. of the membership of the State Medical Association is made up of practitioners of medicine who are members of county societies in affiliation with the State society. The figures which will show this are taken from the published transactions of the two organizations and are authentic. In 1895 the State Medical Association had a membership of 780, 484 of these having membership in county societies. In 1899 the membership of the State Association was 595, a loss in five years of 23 per cent. Of these 595 members, 402, or over 67 per cent., had membership in county societies. Eight county societies in 1899 sent fourteen delegates to the State society who were members of the State Association, and in 1900 one of the nine members of the committee to nominate officers for the State Society was a member of the State Association. In 1899 the presidents of five county societies were members of the Association, and in the same year eighteen County societies elected twenty-six censors who were members of the Association. In twenty-six county societies officers numbering fifty-five were elected who were members of the Association. The State Medical Association has had, during its existence, seventeen presidents, eleven of whom are now living. Of these eleven, eight are members of county societies, two being permanent members of the State society and three are now officials in their respective county societies. How these gentlemen explain to themselves the inconsistency of their dual position the writer cannot say.

The Association was certainly originated by a minority of former members of the Medical Society of the State of New York, and ever since its organization has persistently endeavored to supplant the Society and its county branches, at first in the Legislature, and now in the courts. That the Association has been, and is, the enemy of the Society no one who has knowledge of the facts will attempt to deny. The members of the various county societies in affiliation with the State society who are also members of the State association or any of its local branches, are giving strength to an organization whose sole purpose has been and is the overthrow of the State society, and but for whose efforts the unpleasant relation now existing between the Medical Society of the State of New York and the American Medical Association would have been adjusted long since.

It has been necessary, in treating this subject, to cover considerable ground in order that we might

lead up understandingly to the position we occupy to-day. Much of the space we have devoted to the history of our medical society is given to contemporary history, which is, after all, the part which should interest us the most, because it is history we are making. In our efforts to protect and perpetuate the system of protection to the public health which has grown up in this State under the guidance of the Medical Society of the State of New York and its county branches, it is necessary that we familiarize ourselves with and keep in mind always the various steps by which this system has grown lest we in our ignorance advocate some revolutionary measure which would destroy the work our predecessors gave so much time and effort to accomplish. In order to clearly portray the exact condition of affairs we have written at considerable length in this article, and if we have succeeded in demonstrating to any considerable number the necessity of exercising caution in connecting ourselves with organizations the purposes of which are to destroy the influence of the Medical Society of the State of New York and its county branches, then we will feel that the labor incident to the preparation of this paper has been amply repaid.

A few words more of the aim and purpose of our medical society and we have finished. We can sum this up in a very few words. The original Act incorporating the Medical Society of the State of New York was declared to be a "public act," and its purpose was "to regulate the practice of physic and surgery." The purpose of this State society has always been in this direction; to regulate the practice of medicine in order that the people might be protected from incompetent and dishonest practitioners of medicine. With this purpose in view our Society secured the enactment of the present medical law, which does not personally benefit any medical man or woman. This law benefits the community and this is the only just reason why such laws are ever enacted. As a class we have no right to ask the State to legislate for our especial benefit. The State has no right to pass laws which give to one class of citizens privileges which may be detrimental to the interests of some other class. The State, however, has the right—as demonstrated by the decision of the United States Supreme Court in the case of the appeal of a person who was convicted of illegally practising medicine in this State, through the efforts of our County Society—to regulate the practice of medicine, because on this regulation depends the preservation of the public health.

Political parties may interest themselves in matters of finance and tariff regulation, but no more important subject will ever be brought before the people of this country than the subject of the proper regulation of the practice of medicine and the protection of the public health. The State of New York has placed this matter in the hands of the medical profession, and in accepting this trust the Medical Society of the State of New York and its county branches aim to so conduct themselves as to merit the approbation of all good citizens.

NOTE.—In the preparation of this paper the author has made use of the following works, and desires to express his sense of obligation to their authors.

1. Medical Ethics and Medical Etiquette, published in 1883 by G. P. Putnam's Sons. An ethical symposium of papers by Drs. Alfred C. Post, William S. Ely, S. Oakley Vanderpoel, Lewis S. Pilcher, Thomas Hun, William C. Wey, John Ardronaux, D. B. St. John Roosa, Cornelius R. Agnew, Abraham Jacobi, and H. R. Hopkins, with a preface by Dr. Frederick R. Sturgis, and an appendix by Drs. William Warren Potter, of Buffalo; James Spencer, of Watertown; B. F. Sherman, of Ogdensburg; W. C. Wey, of Elmira; W. H. Bailey, of Albany; Edwin Hutchinson, of Utica; E. V. Stoddard, of Rochester; L. S. Pilcher, and J. S. Prout, of Brooklyn, and A. H. Smith, C. R. Agnew, A. L. Loomis, J. L. Little, H. B. Sands, and R. F. Weir, of New York.
2. The Status of the Medical Profession in the State of New York, by Dr. Henry G. Piffard, published in the New York Medical Journal, editions of April 14, April 28, May 5, May 26, June 2, October 6, and November 24, 1883.
3. Monographs on Education in the United States, by James Russell Parsons, Jr., secretary to the Board of Regents of the University of the State of New York.
4. The minutes of the Medical Society of the County of New York.
5. The Transactions of the Medical Society of the State of New York.
6. The Transactions of the New York State Medical Association.
7. Briefs submitted by Hill, Sturcke and Andrews, Counsel for the Medical Society of the State of New York, and Robert C. Taylor, former Counsel of the Medical Society of the County of New York.

PNEUMONIA: ITS ETIOLOGY AND TREATMENT.

BY D. L. BURNETT, M. D.,

OF SOUTH ROYALTON, VT.

How often have we seen the look of dread and despair on the faces of friends and relatives as we have pronounced the sentence of pneumonia in the sick room. It is stated that nine-tenths of all deaths after the seventy-fifth year are from acute pneumonia (Loomis). It is a disease that all fear, and, therefore, it behooves us to be especially cautious in making our diagnosis too pointed to the patient, unless it seems imperatively necessary, as oftentimes the element of fear as to the outcome of the illness is a prognostic factor of considerable importance. It is much better to remind the attendants that the less often the word pneumonia is spoken in the hearing of the sick one the better will be his chance of ultimate recovery. This fact is true of all severe types of acute diseases, but the condition of the nervous system is such that it is doubly true in pneumonia.

There is something in the sudden onslaught of pneumonia, in its reducing of the strong, healthy, never-sick-man to the weak, despairing invalid within the limits of a short half-hour, that is enough to make the stoutest heart quail. But in no disease is the physician better repaid for close attention and intelligent effort than in the one under consideration. I do not believe that, as yet, treatment offers much in the way of shortening the length of the disease, though in this opinion I may be decidedly with the minority, but I do most firmly believe that the outcome of pneumonia in a large class of cases is most certainly and emphatically dependent on the treatment received. It is true that there are cases which will recover with no treatment, and also cases which no physician, however versatile or learned, can save; but there certainly is a large middle class in which the progno-

sis depends on the physician, attendants and environments.

The consensus of opinion is that lobar pneumonia is caused by a germ, or, speaking more strictly, by two germs, viz., the pneumococcus of Friedländer and the diplococcus of Fraenkel, these cocci not being bacteriologically identical. Moreover, they are accompanied by pus germs, and toxins are rapidly developed, so that in its entity pneumonia is probably a mixed infection. The diplococcus of Fraenkel is found, however, in seventy-five per cent. of cases. It is thought that the pneumococcus of Friedländer is a less virulent germ, but able at all times to produce pneumonia. The diplococcus of Fraenkel, therefore, is the most usual micro-organism found in the malady under consideration. It has been found in the blood, spleen, kidneys and endocardial vegetations of a person sick with pneumonia, and it is also often found in the saliva of healthy persons. In sharp contradistinction to the bacillus of Eberth, which causes typhoid fever and which retains its vitality outside of the body under favorable conditions for many months, the diplococcus is virulent for only a few days when outside the body.

Bronchopneumonia, otherwise catarrhal or lobular pneumonia, is not thought to be caused by the diplococcus of Fraenkel, but may be of a specific nature, as, for example, tuberculous or syphilitic bronchopneumonia. It is often a terminal affection following bronchitis, or, as a complication or sequelæ of the diseases peculiar to childhood or at the other extreme of life, it is extremely apt to occur during or following such severely-depressing diseases as diabetes, nephritis, influenza, etc. Staphylococcus and streptococcus infection are etiological factors of importance. Inhalation, aspiration, and deglutition bronchopneumonias are due, as the names imply, to foreign bodies being carried into the lungs or bronchial tubes and causing the bronchopneumonia by their mechanical or septic action. I do not propose to speak of embolic or chronic interstitial pneumonia.

Treatment.—As in many other diseases the principle of treatment of pneumonia has undergone a complete reversal during the last half century. Then "lung fever," as it was called, was treated by venesection and by *hydrargyrum chloridum mite* in substantial doses. Depletion was the keynote. If the patient had pleurisy—bleed; for dyspnea—bleed; if the heart was failing—bleed; if the crisis was late—bleed, and especially if any complication arose, bleed *ad infinitum*. Now, I doubt whether there are six physicians present who have bled a patient in pneumonia during the last fifteen years. There are instances where bleeding is a benefit if it can be done at the proper stage of the disease, but in most cases the same results may be brought about by measures that do not tend to reduce the strength of the patient. An initial dose of a mild cathartic such as cascara sagrada, is indicated in ninety per cent. of the cases. This, I think, is nearly the first action to be taken in the line of treatment, as it flushes the bowels of all collections of fecal matter, excites the glandular system of the alimentary tract and puts the economy in the best possible condition for the struggle to follow. This should be attended to before any anodynes are used. After the bowels are thoroughly unloaded, put the patient well under opium in some of its various forms and hold him under it for at least two or three days, until the sudden shock to the nervous system is somewhat expended; with due caution this drug may be used in the aged and in young children. In my opinion, the use of internal antipyretics is very seldom required. I have been able to control any excessive fever, as a rule, by cold spongings, and it has seemed with less depression to the patient. It might be in some cases with a persistently high temperature, that cold-water spongings combined with small doses of coal-tar preparations would be of advantage. Leave a clinical thermometer with the family or nurse, if they are intelligent enough to be able to use it, and with the proper instructions the cold spongings may be safely left with them. Allow the patient plenty of liquid drinks, both for his comfort and for their liquefying effect on the products of inflammation.

The chief organ to watch in the treatment of pneumonia is the heart, for if it can be kept up to its work until the obstruction due to inflammatory products in the lungs and the depressing effects of the toxins on the cardiac nerve centers have had an opportunity to subside, the patient has an excellent chance to recover. A very serviceable combination is nitroglycerin, sulphate of strychnine, spirits of camphor, aromatic spirits of ammonia, and spirits vini gallici, to which may be added an opiate if needed. The glonoin has a multiple action as a cardiac and respiratory stimulant and as a dilator of the arterial system. The strychnine may be increased in dose, if needed, until very decided physiological effects are produced, provided the patient can be seen frequently. I am convinced that this drug is often used in this disease with too much timidity. It is a drug that gives us sufficient warning of danger to prevent serious results, and I am sure that I have seen some almost hopeless cases, especially in aged people, recover after the very free use of strychnine. As the disease progresses the amount of the heart and respiratory tonic and stimulant treatment will probably need to be increased. The alcoholics may be well taken in milk, cold tea or coffee, and usually better sipped in small quantities at a time. I am very particular in regard to one point, and that is not to allow the patient to rise on his elbow either while taking nourishment or medicine or while coughing. It puts just so much more work on the heart. Use a feeding-cup for giving liquids, and make the patient expectorate on old cloths which may be burned immediately. The use of expectorants, in the ordinary meaning of the term, is not to be advocated as a routine measure in the treatment of acute stages in adults. Water or liquids will render the products of inflammation less gelatinous,

and cardiac and respiratory stimulants and tonics to assist in expelling them are far preferable to the syrupy cough mixtures so frequently used. If the cough is more than is needed for clearing the throat and upper bronchial tubes, if it is a nerve-cough caused by irritation of the bronchial nerve-endings, it may be well controlled by some preparation of opium and camphor, like Tully's powder or by inhalations of steam and turpentine, or creosote. Usually with this irritable cough there is not much secretion, which fact does away with the theoretical objection that the opium will dry up the secretion. Insomnia is frequently an alarming symptom and, if possible, should be met without a direct recourse to opium. If due to either pain, cough or dyspnea, it should be treated in some of the ways already indicated; if due to the exhausted condition of the patient, by increased stimulation, food often repeated, and sponge-bathing with hot alcohol, ammonia and water, together with dry hot flannel rubbings. Hyoscyamine, grain 1/100, will often have the desired effect, especially if there be a tendency to delirium. Delirium, of itself, in pneumonia, will often furnish the physician with something to keep him busy. The same hot spongings and rubbings, and increased stimulation will be of use as in the insomnia. In case of intense delirium look out for complications; cool or cold applications to the head are often of benefit. It is usually essentially necessary that the attendant does not try to converse with the patient in this condition. In regard to the local means to be employed there exists a wide diversity of opinion from the ideas of former years. The tendency at the present time seems to be to do away with all forms of local irritation in the first stages of pneumonia, and they are used only sparingly in those cases of delayed resolution in the form of numerous small fly-blisters or tincture of iodine or similar remedies.

Neither do local applications of poultices seem to be as much in favor as formerly. I am free to confess that in families in which the physician can be sure that the poultices will be carefully attended to before getting cold and with as little exposure and irritation to the patient as possible, and are made of as light material as can be used, they are a means of great comfort in the first stages and when there are sharp pleuritic pains or a harsh annoying cough. When they are not properly attended to, we only too often see the abuse rather than the use of poultices. A cotton jacket is very convenient for a covering to the chest; it may be easily made from old, thoroughly quilted bed-covering, cut large enough to envelop the chest front and back, notched under the arms, caught together over the shoulders and fastened with tapes and buckles on the sides. The material should be thoroughly aired and dried before a good fire before being used. This serves the main purpose of keeping the chest in as equable a temperature as possible.

The question of nourishment throughout the course of the disease is an important one. Lime-water and milk is an old and valuable means of nourishment. In fact almost any easily-digested food is usually allowable if the patient desires it. One point in this connection is as true in this disease as in others. Never ask the patients if they wish such and such articles. Simply carry the prepared food to them as if it was a matter of course at the time. Usually in this way more food is taken than would be in the other. In pneumonia, the food should be given in small quantities and frequently. During convalescence the keynote of treatment is tonics, especially iron and strychnine, with some of the vegetable bitters. If resolution is delayed, the iodides are of use, especially that of ammonium. Cod-liver oil also is of much value at this time.

ON THE PROGNOSIS OF HYSTERIA: A CONTRIBUTION TO THE QUESTION OF FATAL HYSTERIA.*

By JOSEPH FRAENKEL, M.D.,

OF NEW YORK;

INSTRUCTOR IN NERVOUS DISEASES AT CORNELL UNIVERSITY; PHYSICIAN IN CHARGE OF MONTEFIORE HOME; PHYSICIAN TO HOSPITAL FOR NERVOUS DISEASES.

MUTATIS MUTANDIS, the phrase in which the ancients clothed their ignorance of the anatomy and functions of the brain, still applies to hysteria; *actiologia obscura, pathologia obscurior, anatomia obscurissima.* In obscurity theories are easily fashioned, and small wonder that there are almost as many theories about hysteria as there are human minds busying themselves with the question. No theory has, however, so far been accepted without contradiction, and not one has given satisfactory explanation of all the hysterical phenomena. Considering this obscurity and the theoretical dissensions, the unanimity found in the question of prognosis is astonishing.

The feeling of relief experienced when the functional nature of a case in question is established, after long and arduous differential diagnostic reflections, is well known. This feeling arises not only from the consciousness of having completed one's task, but also from the conviction that in functional disorders the outcome is usually favorable. This alone would indicate how generally accepted the belief is that the prognosis of functional diseases in general, and of hysteria in particular does not call for much study and deliberation. A more thorough examination of the literature of the question lends further emphasis to this belief. One is tempted to say that the general acceptance of such a belief is almost self-evident when treatises like the Twentieth Century Practice and the Traité de Médicine in their chapters on hysteria do not mention the prognosis at all. In other current text-books and manuals, the extreme brevity with which the question of prognosis is settled is somewhat inconsistent with the minuteness with which symptomatology, etiology, therapeutics, etc., are discussed, particularly as the

*Read by Title before The American Neurological Association, 1900.

question of prognosis is an eminently practical one. Here and there suggestions are thrown out that the prognosis of hysteria may occasionally become more serious, and that a fatal issue may terminate a hysterical picture.

During a period of two years I saw three undeniable clinical pictures of hysteria end fatally. Considering the frequency of hysteria, three deaths in two years do not necessarily conflict with the popular opinion already noted; nevertheless these experiences were striking enough to induce me to look more deeply into the question of the prognosis of hysteria.

Concerning this question, authorities at present are divided into two groups. For the majority, hysteria is a disease of good prognosis, fatal issue being rare. In fatal cases death is believed to be due to the fact that the respiratory musculature is involved in the hysterical spasm (spasm or paralysis of the glottis), or is the result of inanition, following long-standing hysterical anorexia, or uncontrollable hysterical vomiting, or, finally, is mediated through direct or indirect forms of suicide.

A smaller number of observers believe that death is under no conditions the legitimate outcome of an uncomplicated genuine hysteria; on the contrary, that such an issue makes the diagnosis hysteria impossible.

From what standpoint, therefore, shall one consider the question of prognosis in a given case of hysteria? In most other diseases we have more or less reliable fundamental principles, and the question of prognosis is answered in an accepted methodical fashion. The prognosis is then chiefly dependent upon the intensity and extensity of the underlying anatomical process. Trustworthy information is furthermore to be had from the known course of most diseases. To a certain extent one may rely upon the positive or probable efficacy of the customary therapeutic procedures. Finally, the individual equation of the patient, the explicable or inexplicable individual structure and manner of the reaction of the tissues, are of some value in this respect.

Concerning hysteria, we are still very far from a plausible idea of a possible anatomical foundation, and are therefore unable to construct the prognosis upon the only safe basis, *i. e.*, that furnished by pathological anatomy. But, in many other respects also, we are less amply provided with reliable and unequivocal facts in hysteria than in other diseases.

It has probably occurred in every one's experience to have seen cases of severe hysteria, with considerable hereditary taint, recover under scarcely any therapy, and, on the other hand, cases of apparently mild hysteria, without traceable hereditary taint, succumb to incurable illness in spite of all treatment. Frequently hysterical symptom-groups have defied all imaginable therapeutic procedures for a long time, and then suddenly have yielded to a seemingly unimportant and inexplicable maneuver.

Cases occur, although rarely, which to all appearances seem to warrant an unconditionally favorable prognosis, and which take a sudden turn for the worse, or even end fatally, much to one's surprise and dissatisfaction, without leaving tangible indication for future guidance.

Naturally the inquiry is forced upon one, whether it is entirely impossible to foresee these accidents at least approximately, and, upon what guiding principle the prediction of the same is to be built. An answer seems to me extremely unsatisfactory, as the facts at present at our command do not permit the formation of a clearly-defined outline. An experienced observer will frequently guess the right course and future development of a given case; but even he will sometimes go amiss, and much more so will the less experienced.

For the sake of reaching a better conclusion, it seems advisable to divide the foregoing general question into special ones, and to find answers to the following: (1) Is hysteria curable at all? (2) Upon what conditions does the curability or incurability depend? (3) Is hysteria ever fatal?

Hysteria is just as curable as syphilis or tuberculosis are. It is frequently observed that the evidences of activity of any of these diseases abate, either temporarily or permanently. Their previous existence can usually be inferred from the so-called stigmata, general or local signs congenitally imprinted upon the patient, or left on his body by the active stage of the disease, in form of phthisical habitus, syphilitic scars or hysterical stigmata. Thus is prepared a soil upon which, and caused by discoverable or undiscoverable additional etiological factors, the same or other hysterical symptoms may spring up again at any time, although not necessarily so. Some hysterical patients after recovering from one attack of hysteria may remain exempt from hysterical phenomena the rest of their lives.

To determine the conditions upon which the curability of hysteria depends, we naturally, at the present anatomical era of medicine, turn to the anatomy for aid. In view of the fact that we are still awaiting the anatomical solution of hysteria, and that at present no generally accepted anatomical basis is known, we cannot expect reliable support from this point of view.

In ancient times the uterus was held responsible for hysteria; in the middle ages the devils; and in more modern times, with apparently equal justification, the brain or the sympathetic nervous system.

For purely clinical reasons, and for reasons the analysis of which would lead us to-day too far into the sphere of splanchnic physio- and pathomechanics, the last view seems to me to be the most probable. Whichever it is, and wherever the root of the disease, the superstition that hysteria is merely a malady in the sense of Molière is at the present time abandoned by earnest thinkers. And if this is so, then, in spite of the unknown anatomy, hysteria must become subordinate to the

laws of general pathology, which teach that the tissues are subject to more or less reparable or entirely irreparable changes, and thereby lead to various disturbances of function.

Evidently, then, the clinical symptoms resulting from these disturbances are accordingly either fluctuating and evanescent, or stable and permanent. Therefore, whenever the abatement or fluctuation of the main symptoms is in accord with the first acceptation, *i. e.*, a reparable damage of structure, the prognosis is a better one than when in the midst of the fluctuation of symptoms a stationary phenomenon indicates a deeper structural change.

At times this very fact will be a guide to the fountainhead of all hysterical weal and woe upon which a causal and more direct therapy can be built that may change the prognosis for the better.

One could proceed with greater safety if, in the future, more attention were paid to the purely clinical side of hysteria, at least so long as we are waiting for an anatomical salvation. Clinically regarded, everything concerning hysteria is scattered about pell-mell, and individual clinical groupings receive only slight appreciation. There certainly is a clinical, perhaps also an anatomical, difference between a purely mental and a purely somatic hysteria. A hysterical monoplegia and a hysterical pseudoperitonitis are assuredly not of equal significance. An attempt at an analysis of the symptomatological kaleidoscope, hysteria, might in many respects be instructive. In the literature very little is to be found prepared for a nosological classification of hysteria.

Conforming to the teachings of La Salpétrière, Tourette distinguishes a paroxysmal or pathological hysteria from an interparoxysmal or physiological one. The intervals between the paroxysms are of different duration, and each paroxysm ought naturally to exhaust itself. Therefore, if sufficient care is exercised, dangerous accidents during an attack can almost always be prevented; and when proper therapeutics are applied during the intervals, these cases generally promise a fairly good prognosis.

From the etiological point of view, so-called traumatic hysterias can be sharply separated from all the other forms. The prognosis of the first named could fill a considerable pamphlet. The fact that these forms are often copied by simulation, to a degree amounting to positive disguise, makes the question the more difficult. Generally, traumatic forms of hysteria, particularly in men, give a *grave* or *unfavorable* prognosis. External accidents, tardy application of the proper therapeutics, or their frustration through lengthy legal proceedings, allow the malady to take root too deeply and future eradication becomes at times impossible.

Frequently a distinction is made between monosymptomatic and polysymptomatic forms of hysteria. According to my experience the monosymptomatic cases are generally more obstinate than the polysymptomatic ones, although at times the contrary may also be true. The first would harmonize with the theoretical acceptation that stationary symptoms seem in all probability, to indicate severer anatomical lesions.

From a general clinical point of view, hysteria could be separated into three principal groups, which, however, like all things in Nature, are not marked by fixed boundary lines and can show many interchanges and mutual displacements. As belonging to these groups can be enumerated (1) predominantly mental forms, hysterical psychoses with more or less pronounced somatic symptoms; (2) predominantly cerebrospinal forms; symptoms of this group are mainly composed of phenomena of irritation or paralysis of motor or sensory apparatuses supplied by the cerebrospinal system (monoplegias, hemiplegias, paraplegias, tremors, contractures, ocular symptoms, etc.); (3) predominantly splanchnic forms; the symptoms of this group are composed mainly of phenomena of irritation or paralysis of motor or sensory apparatuses supplied by the splanchnic or sympathetic nervous system (vomiting, constipation, diarrheas, meteorismus, tympanitis, phantom tumors, ulcerations, edemas, etc.).

Around all these three groups is wound the symptom-complex of hysterical seizures—*grand ou petit mal hystérique*—as a band of unification. The ultimate analogous nature of all these groups is shown by the fact that the symptoms of every group are found occasionally intermixed or supplanting each other, permanently or temporarily. The main picture, however, is chiefly composed of the symptoms of one of these groups. The last group, the predominantly splanchnic form, is at present not well known. Thus far but few observers have espoused the cause of vegetative neurology, and this branch seems to me best fitted to throw eventually more light upon the question of hysteria.

Finally, in hysteria, as in other diseases, one must separate the genuine forms from the symptomatic ones. Hysteriform symptom groups and individual hysterical symptoms are known to be frequent accompaniments of any imaginable organic disorder. The hysterical phenomena and the underlying disease stand to each other in a twofold relationship; the hysterical symptoms are either an accidental addition to the clinical evidences of the organic disease, or they are essential clinical evidences of the organic disease conditioned by the same. This last causal relationship between organic disorder and hysteriform symptoms is not at all times easily demonstrable. Particularly are toxemias, initial forms of local or general cerebrospinal or splanchnic arteriorsclerosis, frequently expressed by hysteroneurasthenic symptoms.

The prognosis of the first two groups, *i. e.*, the predominantly psychical and the predominantly cerebrospinal forms, is, according to my experience, generally more favorable than the prognosis of the third group, the predominantly splanchnic form, which seems the most obstinate and occa-

sionally even dangerous. In the last mentioned symptomatic group the prognosis depends naturally upon the fundamental disease.

I. Mayer and Wunderlich first called attention to the question of fatal hysteria by reporting cases which they called acute fatal hysteria. After severe critical examination these cases cannot be left in the rubric of hysteria. The cases of Mayer resemble cases of delirium acutum, and in those of Wunderlich short hysterical prodromata were soon followed by a fatal issue under enormous hyperpyrexia. In addition to the papers just mentioned I was able to find only ten studies on the question of fatal hysteria. Two are of a more general character.

Fournier[1] calls attention to the fact that in spite of the generally accepted opinion of the benign nature of hysteria, fatal cases are by no means rare. In such cases death ensues, as already stated, from spasm of the respiratory musculature. Long-continued hysterical anorexia or hysterical vomiting have not uncommonly the same result. Fournier furthermore thinks that hysterical angina pectoris may sometimes be fatal, and that carelessly performed hypnotic séances can also result fatally. Fournier also includes in this category death which has been observed occasionally to follow laparotomies, particularly hysterectomies. Maguire[2] in a short address before the London Medical Society, the original of which I could not look up, refers simply to death resulting from so-called functional disease, explaining it by the supposition of a state of exhaustion of the gray matter. Two further papers by Philippi[3] and Frideberg[4] are of little value for the question at issue, as in both cases death did not result from hysteria proper, but from complications arising after the patients had swallowed needles. The remaining six papers contain reports of cases of hysteria with fatal issue.

Robert[5] reports a case the clinical history of which is not sufficiently complete and convincing. Moreover, the autopsy of the case is missing, and therefore a final judgment is not permissible. The same holds good for the cases of Walsche[6] and Given[7]. Given's case resembles greatly a case of acute encephalitis. L. C. Allen[8] describes a case of tonsillitis (Quincy) and typhoid fever in which convulsions and somnolence developed. These the author regards as hysterical, without sufficient proof, however. A subcutaneous injection of a larger dose of apomorphine, was soon followed by a fatal issue, and the author himself is in doubt as to the cause of death; whether it was the injection or a spasm of the glottis. An autopsy was not made.

Stretton[9] calls attention to the possibility of a fatal termination of hysteria and reports two cases. The first is a case of stupor with a very meager clinical history and negative autopsy findings. The second case has likewise a scant history and no autopsy report. The author thinks that the usual manner of death in hysteria is coma. Finally, the two cases of Fairbrother[10] give no fuller information about the question of fatal hysteria. The first case seems to be a mixture of pneumonia (?) and tetany (?) and has no autopsy report. The second case is not clearer and has likewise no anatomical explanation.

As mentioned in the introduction, I have in three instances seen death result from hysteriform conditions. These instances stated as briefly as possible are the following:

Case I.—A. H., forty-two years of age, single, American, was brought from the Mt. Sinai Hospital to the Montefiore Home, January, 1897, suffering from severe hysteria. Her family history was negative and her present disease dated back nine months. There was no attributable cause for the onset of the present symptoms. At the time of admission to the Montefiore Home the chief symptoms were emaciation, anorexia, vomiting, and obstinate constipation. Pulse and temperature were subnormal. Repeated objective examinations at both institutions revealed nothing suggestive of organic disturbance. While at the Montefiore Home no considerable change in the picture took place. The patient took only a small amount of nourishment, and after two weeks she died suddenly, apparently of exhaustion. The autopsy revealed the following: Small hemorrhagic erosions in stomach, scattered spots of ulceration in small and large intestine. These ulcerations were dark and parchment-like, very similar in appearance to trophic ulcerations of the skin. Two small intramural fibromata of the uterus were found. The brain and spinal cord showed no changes to the naked eye, excepting that the meninges were unusually dry. The result of the microscopic examination is not trustworthy, because the patient was embalmed prior to the autopsical examination, and on this account the changes found, although very slight, cannot be considered genuine, and the possibility of their being artifacts must be born in mind. The sympathetic nervous system was not examined.

Case II.—M. W., forty-three years of age, married, American, is the descendant of a fairly healthy family. Without any assignable cause, the present disease began eight months ago with pain in the lower extremities and difficulty of locomotion. She soon became very much worse, so that she was unable to be up and about without assistance. At the time of the examination she complained of being very nervous, easily excited and fatigued, and further of frequent and intense pain migrating all over the body, particularly on the left side. She further suffered much from moody functions of the circulatory and alimentary tracts. Sensation of heat and cold, profuse perspiration, and excessive dryness of the skin alternated rapidly and were very distressing. Voraciousness and anorexia, belching and vomiting, constipation and diarrhea were unaccountable in their appearance. Often severe palpitation of the heart awakened the patient at night. Vesical and rectal tenesmus were occasional symptoms. The patient was free

from signs of degeneracy, of fair build, and well nourished. In the left breast a small tumor was found, as large as a hazelnut. This tumor was adherent to the skin covering it, and led to a retraction of the mammilla. The tumor was believed not to have increased in size during the last four years, and, according to respected surgical opinion, its nature was believed to be carcinomatous. With the exception of a coated tongue, occasional irregular heart action and some scattered analgesic spots on the body, no further objective findings could be made out. After three weeks of unsuccessful treatment, the patient passed into other hands, and died suddenly four weeks later under symptoms of acute paralysis of the intestines. No autopsy was made.

Case III.—The detailed account of this case is to be found elsewhere*. I shall only mention in this connection that the patient came of a healthy family and had been in good health up to the time she came under my treatment, one year prior to her death. During this time she was treated for undeniable hysterical symptoms, without success, and died suddenly within thirty-six hours with symptoms of pseudoileus. The autopsy showed a cold abscess, a little larger than a pin's head, of the left fourth rib which infiltrated the left-sided thoracic sympathetic chain.

From the foregoing, the inference is permissible that in hysteria death is due to: (1) Spasm or paralysis of any part of the respiratory mechanism. Whether this is simply the result of the temporal prolongation of the spasm, and the thereupon dependent secondary paralysis of the central mechanism of these functions—thus by timely interference avoidable—or analagous to the last mentioned case, the result of irremovable lesion of the sympathetic innervation, is thus far not determinable. (2) To inanition resulting from prolonged hysterical anorexia or uncontrollable vomiting. Here, also, it cannot be determined whether death is the result simply of starvation or the result of a more deeply conditioned disturbance of the mechanism of resorption. (3) To paralysis of the circulatory or alimentary apparatus in the last case under the picture of a pseudoperitonitis, or a pseudoileus as in the second and third of the above reported cases.

The third case cannot in the light of the present teaching be rubricated absolutely as hysteria. According to Nothnagel and others only such cases and symptoms should be called hysterical in which thorough clinical and anatomical investigation fail to reveal any trace of organic disorder.

Whether further experiences in this subject will not prove finally that most of the cases of so-called fatal hysteria are the result of anatomical occurences, similar to the one described, the future will show. In that case most of them will then have to be looked upon as secondary or symptomatic forms of hysteria, and how much there will be left then as genuine hysteria "sensu strictiori" is an open question. For the present, the possibility of a fatal issue in genuine uncomplicated hysteria is still very doubtful.

However, it seems reasonable to state that in hysteria, death when it occurs, is due to irritation or paralysis of splanchnic or vegetative functions, and that a case of hysteria with more or less constant and prevailing splanchnic or vegetative symptoms is from a prognostic standpoint both *quo ad valetudinem et vitam* to be adjudged very cautiously.

MEDICAL PROGRESS.

Inguinal Hernia in the Female.—W. B. COLEY (*Annals of Surgery*, Dec., 1900) believes in the removal of the sac in all cases and denies the desirability of transplanting the round ligament. The following method was employed in 123 cases recorded; the incision is made one-half to three-quarters of an inch above and parallel to Poupart's ligament, and should extend nearly to the level of the anterior superior spine; the aponeurosis of the external oblique is split up well over the internal ring, and dissected back to the edge of the rectus on the inner side, and on the outer, sufficiently far to expose the thick fold of Poupart's ligament; if the sac is sought for high up just below the edge of of the internal oblique muscle, there will be no difficulty in finding it; after the sac has been dissected from the round ligament and thoroughly freed well within the external ring, it is transfixed and tied off with catgut; the wound is then closed in three layers as in Bassini's method, a medium-sized kangaroo tendon being used for all buried sutures, and catgut for the skin; in the deep layer, interrupted sutures, usually four or five in number, are introduced from above downward, bringing the internal oblique and transversalis muscle over to Poupart's ligament; the round ligament is allowed to drop back into the lower angle of the wound, and as it approaches the pubic bone it is so small that it requires much less space than the cord in the male; the aponeurosis is now sutured with a continuous suture of kangaroo tendon, about the size of No. 1 catgut; the skin is closed without drainage, and the wound dressed with iodoform gauze and moist bi-

chloride gauze, 1-5000; the patients are kept in bed from ten to fourteen days, when they are allowed to go about, a spica bandage being kept on for two weeks longer, at the end of which time support of any kind is discontinued. Not one relapse occurred in all the cases so treated.

Paroxysmal Delirium and Auto-intoxication.—(1) The symptoms manifested by auto-intoxication are so varied that the condition is frequently not recognized, or when the nervous symptoms are very pronounced the case may be diagnosed as typhoid, malaria or meningitis. W. C. HOLLOPETER (*Internat. Med. Mag.*, Dec., 1900) analyses several cases recently observed which manifested peculiar delirious conditions due to auto-intoxication. One was a boy, four and a half years old, taken acutely ill with fever and tendency to nausea. The bowels were regular; temperature 104.5° F.; he was very restless. In the evening the child became violently delirious, remained so for several hours, and finally fell asleep exhausted toward morning. This was repeated for three or four evenings. The Widal test was negative. The urine showed enormous quantities of indican and was lithemic. After several high enemata a large quantity of foul-smelling undigested food was passed and the symptoms disappeared rapidly. Two other cases very similar in nature are given to illustrate what a decided influence upon the cerebral condition intestinal intoxication may have.

Wounds of the Heart.—L. L. HILL (*Med. Rec.*, Dec. 15, 1900) states that wounds of the heart may be penetrating or non-penetrating, injuring the cardiac wall or opening a cavity; the chief dangers from the former are shock and injury to a coronary artery; ninety per cent. are penetrating; the right ventricle is most frequently injured and the left auricle is least so; auricular wounds are more fatal than ventricular ones, and injuries to the apex are less dangerous than either; a needle puncture will rarely cause hemorrhage from a ventricle, but excessive bleeding is likely to follow a like injury to an auricle; a wound inflicted during diastole is less dangerous than a similar injury during systole; perpendicular wounds are more fatal than diagonal ones, and those of the right heart bleed more profusely than those of the left. The presence of the foreign body in the heart, the size of the wound, the number of the wounds, the connecting of cavities, the attending syncope, the involvement of Kronecker's coördination center are important factors in determining the outcome; pericarditis, myocarditis, endocarditis, and empyema are frequent secondary complications. The treatment consists in exposing the wound as far as practicable and closing the wound of the myocardium with interrupted sutures which should be placed close together and not involve the endocardium; silk is preferable to any other material; the needle should be the same as that used in suturing the intestines, and the sutures should be passed and tied during diastole; the first suture may be used to steady the heart and facilitate the passage of the others; in sewing the pericardium either interrupted or continuous sutures may be used. It is well to remember that when the wound heals there is a possibility of cicatricial stretching and subsequent rupture of the heart cicatrix.

Flechsig Treatment for Epilepsy.—The unfavorable reports on Flechsig's method for the treatment of epilepsy, namely, the so-called "Opium-bromine" cure, have prompted E. MEYER and C. WICKEL (*Berliner Clin. Woch.*, No. 48, 1900) to give to Ziehen's modification of this treatment a thorough trial in the psychiatric clinic at Tübingen. The particulars of the modified treatment are herewith given and it will be seen that they consist chiefly of the gradual increase of the opium to the rather low maximum of 15 grains of the powdered drug three times a day, besides careful regulation of the diet and methodical cold-water treatment. The initial opium dose is about 1 grain of the powder three times daily. On the third day each dose is increased by one-fifth grain; on the fifth day the increase is another one-fifth grain for each dose and so on for every second day. When the fifty-first day has arrived, the patient is taking about 5 grains of the powder three times daily. This is only given on that one day. On the succeeding fifty-second day 90 grains of mixed bromides are given to the patient to be increased every second day by 15 grains until 135 grains a day are reached at which point it remains for some time. From the beginning of the treatment, half an ounce of dilute hydrochloric acid (grams 3.400) is administered after each meal. Alcohol, coffee, tea, bouillon, bologna, all spices, pepper, mustard and vinegar are absolutely withheld, while even salt is reduced to a minimum. Meat is given but sparingly, the chief nourishment consisting of meal soups, eggs, rice, and the various pastry products together with a little fruit and fresh vegetables. From the first day of the treatment, the patient is to take cool baths before the evening meal—each bath to last about ten minutes and to be of a temperature of 86° F. These baths are gradually to be reduced to one minute at 70° F. After this temperature is attained, the baths are again increased to three or four minutes each and later to six minutes. They are then continued until the bromine treatment has begun when for the first week of which they are omitted. After this they are again begun exactly as in the initial period of treatment. The patients are to be weighed every third day and pulse, temperature and respiration carefully taken. The bowels are to be regulated, if necessary, by enemeta and massage and never by means of cathartics by mouth. Cases are then cited by the authors showing their success by these means—success which was never attained by bromine alone. The attacks were lessened both as to frequency and severity and the corporeal as well as the psychic condition of the patients markedly improved.

Acromegaly and Giantism.—J. HALL PLEASANTS (*Maryland Med. Jour.*, Dec., 1900) reports a

case of acromegaly and giantism in a negro between twenty-five and thirty-five years of age, in whom "almost none of the symptoms of acromegaly have been present" and who is only 6 feet 2 inches tall. The history, given in detail, shows that the man was a high-grade imbecile, that his hands were very large but not spade-like in shape, and that his feet were enormously enlarged, measuring 12½ inches in length and 12¾ inches in circumference around the ball of the foot. The toes were very long, the great toe being enormous. The patient has always gone barefoot because he could never get shoes sufficiently large. Radiographs showed that in the hands and feet there was a general enlargement of all the bones, both in length and circumference, involving the shafts and epiphyses. On the terminal phalanges of both the hands and feet there was a marked epiphyseal "turfing" of the bone as in acromegaly. The bony framework of the upper part of the chest was massive, the chest being somewhat sunken. There was a marked kyphosis of the spine in the cervical region and also a slight degree of scoliosis. The clavicles were not enlarged. The spinous processes of the cervical vertebræ were thickened and enlarged. The bones of the face were thickened and enlarged. The thyroid gland was apparently atrophied. The muscles were everywhere flabby. There was an enlargement of the penis. The deep reflexes were somewhat exaggerated. There were no subjective symptoms. The writer discusses the two theories on the relationship of acromegaly and giantism and thinks that the examination of this patient suggests an association of many recognized features of both acromegaly and a certain type of giantism. A complete table of measurements of this patient is given.

Three Varieties of Membranous Angina.—It is a well-established fact that the diphtheria bacillus is not the only micro-organism capable of producing a pseudomembranous inflammation. The condition of the membranes in these varieties of pseudomembranous inflammations is not dissimilar to that produced by the Klebs-Loeffler bacillus. It may be impossible to distinguish the constitutional disturbance from that usually accompanying a severe case of diphtheria. The micro-organisms other than the Klebs-Loeffler bacillus capable of producing such an inflammation are the streptococcus pyogenes, the micrococcus of sputum septicemia, and oidium albicans. A Klebs-Loeffler infection is known to vary a great deal in its clinical manifestations, and these other organisms can also produce a clinical picture varying from a mild sore throat to a fatal disease. WILLIAM T. RUSSELL (*Buffalo Med. Jour.*, Dec., 1900) says that the oidium albicans has never produced a membranous condition of the tonsils, in the experience of the Buffalo Bureau of Bacteriology, which has resulted fatally, but that streptococcus and sputum septicemic infections have been frequently noted and followed in some cases by death. He gives in detail the history of a severe streptococcus tonsillar infection, and also a brief history of a case supposed to be a case of tonsillar diphtheria, but which examinations of the cultures and membrane showed to be an inflammation caused by the micrococcus of sputum septicemia. The latter patient died although antitoxin had been administered at the outset of the disease. The writer arrives at the following conclusions:

(1) The streptococcus pyogenes and the micrococcus of sputum septicemia can produce membranous anginas, accompanied by physical disturbances sufficient to result in death. (2) The oidium albicans produces pseudomembranous exudates easily mistaken for a Klebs-Loeffler inflammation. (3) The only positive means of determining a Klebs-Loeffler infection is by the microscope. (4) From the sanitary standpoint, as regards quarantine, anginas due to the streptococcus pyogenes, micrococcus of sputum septicemia and the oidium albicans, require little consideration.

Laryngeal Tuberculosis. — The suffering which is caused by this most distressing lesion is probably equalled by few other diseased conditions, and so little success has been had in treating it that new ideas are always welcome in the hope that some remedy may be found to stop the ravages of this destructive process. R. D. COHN (*Med. Rec.*, Dec. 22, 1900) says that the disease begins as an infiltration in the deeper layers of the submucosa instead of on the surface as some believe, and it gradually works toward the surface until granulations form over it and these subsequently break down into ulcers. In the primary stages of infiltration and granulation phonation may be interfered with by the swelling, which disappears later when ulceration begins, and a return of voice, though appearing as an improvement, really means an increase in the extent of the process. In the treatment of the disease it should be divided into three stages. In the first stage only localized areas of infiltration or ulceration occur in an otherwise healthy larynx. The only rational means of treating the infiltrations is by the use of the curette after a ten- to twenty-per-cent. cocaine spray has been thoroughly employed. Applications to the mucous membrane are of no avail, for the process is more deeply seated. Insufflations of iodoform or aristol are then made and a second curettage in seven to fourteen days. Ulcerations are best treated by cauterization with a fifty- to eighty-per-cent. solution of lactic acid, rubbed so energetically into the ulcer that a brownish or blackish eschar appears. Cocainization must precede the operation and insufflations are used for one to two weeks until the slough has come away and another cauterization is indicated. In the second stage in which extensive ulcerations occur and a cure is beyond hope, the antiseptic treatment is more appropriate. Inhalations of one- to three-per-cent. carbolic or applications of a ten- to twenty-per-cent. solution of menthol in olive oil prevent a secondary infection which so

often causes rapid swelling, dyspnea and dysphagia in the last stage. In the third stage morphine and cocaine should be freely used and tracheotomy performed if necessary.

Congenital Unilateral Ptosis with Associated Movements.—The rarity of this singular condition makes a case reported by FREDERICK KRAUSS (*Phila. Med. Jour., Dec.* 15, 1900) of interest. The patient was a boy aged six years, whose mother noticed when he was born that the left side of his face was thin and poorly developed, and that there was complete ptosis of the left eyelid. The characteristics in detail are: (1) Complete ptosis of the left lid upon attempted binocular vision. (2) Complete elevation of the left lid upon closure of the right eye, and instant return of the ptosis upon opening the right eye. (3) Partial elevation of the left lid upon opening of the mouth, extreme elevation upon added protrusion of the tongue. (4) Failure of left superior rectus to draw the eye up synchronously with the elevation of the deficient lid. Especially marked was this when the right eye was also open, the lower edge of the left corner being about 3 mm. below that of the right eye. (5) Irregular movements of the eyeball; an absence of regularity in the actions of the extrinsic muscles of the eye as associated with those of the other eye. Krauss thinks that these conditions indicate (*a*) a preference of the psychical impulse to travel from the brain to the third nerve-center of the left side (thus raising the right lid), (*b*) a deficient connection between the third nerve-centers or fibers with each other (producing unsymmetrical action), and (*c*) an abnormal connection between the centers of the fifth nerve and the third nerve-center on the right side of the brain (causing elevation of the left lid with the protrusion of the tongue). The fact that the congenital lesion, the complete ptosis, improved so that the boy can voluntarily raise the lid and keep it open most of the time, proves that the connecting fibers of the third nerve were merely deficient and not absent. The treatment consisted of strychnine sulphate, gr. $^1/_{120}$, t. i. d., p. c., and the occlusion of the right eye during a portion of each day.

Electrical Treatment of Uterine Fibroids.—G. C. SEGUR (*Phil. Med. Jour.*, Dec. 15, 1900) reports in detail three selected cases to illustrate his experience with this treatment, and formulates his conclusions as follows. (1) Electricity properly applied may be considered a specific for the treatment of uterine fibroids. (2) A moderate dosage, 40 to 50 milliamperes, applied for twenty to thirty minutes, relieves pain and influences a diminution in size. (3) There are no dangers to be feared from its use if carefully conducted. (4) Puncture is not necessary in order to obtain practical results. (5) No serious operation should be undertaken until after electricity has been tried.

Angina Due to Friedlander's Bacillus.—An unusual case of recrudescing angina is reported by E. MAYER (*N. Y. Med. Jour.*, Dec. 22, 1900), who has been able to find only twelve similar cases in the literature upon the subject. The patient's history was reported in 1899 before the American Medical Association as a case of chronic diphtheria, but careful and thorough examinations have subsequently cleared up the diagnosis. The patient was a woman, twenty-one years old, and for several years has been troubled with the appearance of a membrane which recurs two or three times a week, lasting one or two days, and then entirely exfoliating of its own accord, leaving the throat in an apparently healthy condition. It always covers the palate and sometimes the entire pharynx, is pearly white when developed, with numerous fine perforations. The attack begins with a sense of tightness, the soft palate becomes opaque and a very thin, adherent membrane may then be seen. In a few hours the membrane becomes thick and the suffering is very great, but can be relieved by making gashes into the membrane. No discomfort is afterward felt and exfoliation occurs leaving a reddened, but not bleeding mucous membrane. Careful bacteriological examinations by Dr. Lartigau showed the presence of the bacillus of Friedländer in all the cultures made and a practical absence of all other microbic species. The diagnosis is usually not very difficult, for the only other very similar condition without symptoms is leptothrix which may be excluded by the microscope. Treatment seems to be of no avail, but the case reported has recently been perfectly comfortable by the use of an alcoholic solution of orthoform.

Catalepsy.—The cataleptic state is one which is somewhat rare in occurrence in general practice, although it is observed rather frequently in asylums for the insane. G. W. NORRIS (*Phila. Med. Jour.*, Dec. 15, 1900) reports an interesting case of this disorder in a young man, twenty-three years of age, an inmate of the Pennsylvania Hospital for the Insane. This patient, a student, became very despondent after a failure to pass certain examinations. He continued to worry, ate poorly, and lost a good deal of flesh. One day he was found pounding his head against the wall. Six months later he became violent and destructive, and had to be restrained. He refused to dress or undress or help himself in any way. He repeatedly soiled clothes and the bedding with his discharges. He had not been heard to speak in six months. His limbs offered no resistance to movements and remained in any position in which they were placed for considerable periods. Because he was found masturbating, he was circumcised and blistered, and the habit checked. For nearly two years the patient's condition remained practically unchanged, although physically he had been considerably built up by food tonics, etc. Several times he screamed loudly and once replied intelligently and volubly to an attendant who scolded him. During twenty-two months the patient has never relapsed from his cateleptic condition. The length of time his limbs would remain in given positions varied from day to day during this time. While his limbs were

placed in a grotesque position, his face would be void of expression, with upturned eyeballs and a slight quiver of the lids, suggesting the almost total suspension of intelligence and oblivion to his surroundings. He would make no voluntary effort, although he swallowed food when placed in his mouth. When left to himself he would gradually lean against some object for support, his chin would sink to his chest, and his arms would dangle at his sides. His general appearance at such times, with his pale, clammy skin and scarcely perceptible respiration, was that of a corpse. On examination his knee-jerks were found to be much exaggerated. The conjunctival reflex was present, but there was no response to deep puncture of the skin in any part of the body. The pupils were normal. There was a slight divergent squint. Circulation was sluggish and the temperature was slightly subnormal. The writer discusses the etiology, duration, frequency, prognosis, and the treatment of this condition, and thinks that this patient will probably emerge from this state in time, but with probably more or less resulting dementia. Some photographs illustrate constrained positions in which the patient remained from twenty minutes to one-half an hour.

THERAPEUTIC HINTS.

Turpentine in Skin Disease.—For psoriasis, eczema and hyperemia Crocker recommends:

℞ Ol. terebinth. rect 0.7-2.0 (♏ x-xxx)
Ol. limonis .....0.12 (♏ ij)
Mucilag. acaciæ... ..15.0 (ʒ ss)
Aqua .....15.0 (ʒ ss)

M. Sig.: A teaspoonful three times a day immediately after meals. One quart of barley-water to be drunk every twenty-four hours.

Pediculus Pubis.—Cut hair short and saturate part with kerosene oil for twenty-four hours. Take a hot soap-and-water bath and apply mercurial or betanaphtol ointment. Shoemaker recommends for any form of lice:

℞ Betanaphtol..... 4.5 (ʒ i)
Cologne water.....120.0-180. (ʒ iv-vi)

J. M. Anders in Practice of Medicine.

Acute Aortitis.—Gilman Thompson advises absolute rest, ice-bag over aorta, aconite and opium, and the inhalation of four or five drops of ethyl iodide to control dyspnea.—*Practical Medicine.*

Gastric Myasthenia.—Massage should not be used to evacuate the stomach until the excessive fermentation is under control, write Van Valzah and Nisbet, but it then may be employed regularly four hours after the evening meal. Electrical treatment during short sittings with strong currents, and following lavage or one or two hours after breakfast, promotes digestion and the evacuation of the stomach. All constriction about the waist should be removed, and the thin, weak abdominal walls and overweighted stomach, supported by a snugly-fitting bandage. Digestion depends on the integrity of the intestinal functions, so the diet must be of small bulk, resistant to fermentation, and capable of ultilization by the intestines. Meats, fish, and the whites of eggs, finely divided, form the staple diet. Meat jellies, fresh butter in moderation, rice and wheat cereals and dry toast may be allowed, and as much as a single glass of water at each meal. Sweets, fruits and milk must be excluded. A little whiskey or brandy may be permitted. Lavage is the classical remedy and in retention is best performed before breakfast. The stomach should be thoroughly washed out with worm, boiled water containing salicylic acid, 1-1000, boric acid, 1-100, potassium permanganate, 1-1000, borax, 5 per cent., or benzoate or salicylate of sodium, 1 per cent., then with:

℞ Ac. borici..... 4.0 (ʒ i)
Ac. salicylici ..... 1.3 (gr. xx)
Aquæ .....500.0 (O j)

In a few cases in order to secure sleep, to give a long rest to the stomach, and to control obstinate fermentation, it is necessary to perform lavage at night, as late as possible so as to avoid evacuating the evening meal. Antifermentative drugs are of very little use.—*Diseases of the Stomach.*

Chlorine Compounds.—Chlorine water, chlorinated soda, and solutions of chlorinated lime, writes Bartholow, are employed locally in scarlet fever, diphtheria, aphthæ, and gangrene of mouth and fauces. They remove fetor and are also antiseptic. A gargle or mouth-wash would be:

℞ Aq. chlori..... 15.0 (ʒ ss)
Aq. dest..... 90.0 (ʒ iij)
Syrupi..... 15.0 (ʒ ss)

Or

℞ Calic. chlor..... 2.0 (ʒ ss)
Mucilag. acac..... 15.0 (ʒ ss)
Aq. dest.....105.0 (ʒ iiiss)

To correct fetor of the breath the following may be used:

℞ Calcis chlorat .....12.0 (ʒ iij)
Aq. dest.
Alcohol.....aa. 60.0 (ʒ ij)
Ol. rosæ.....gtt iv.

M. Sig.: A teaspoonful to a tumblerful of water.—*Materia Medica and Therapeutics.*

Peptonized Milk.—A pint of milk is diluted with one-fourth water, and heated to 140° F. Two or three teaspoonfuls of liquor pancreaticus and sodium bicarbonate, gram 0.7 to 0.13 (gr. x-xx), are added and the mixture poured into a covered jug and placed under a "cozy" to keep up the heat. After an hour or an hour and a half the product is boiled for two or three minutes. It can then be used like ordinary milk.—*Bartholow in Materia Medica and Therapeutics.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE PROPHYLAXIS OF GASTRIC ULCER.

WHILE the etiology, pathology and treatment of gastric ulcer have been the subject of extended discussion, very little has been written about the prophylaxis of this affection. Ulcers with the characteristics of the conical ulcers that occur commonly in the stomach are found in but two other parts of the digestive tract, in the duodenum and in the lower end of the esophagus. As these parts, like the stomach, are frequently bathed in gastric juice, it is evident that some change in this fluid is the underlying cause of this type of ulcer. The comparative rarity of gastric ulcer shows that this change in the gastric secretion is only the predisposing cause. There must be an immediate cause for the production of the ulcer. These immediate causes can be guarded against.

There are two general conditions in which gastric ulcer are especially prone to develop—anemic and subseptic states, by which latter state is meant a condition in which, owing to the presence of a purulent focus somewhere in the body, septic material finds its way in small amounts into the circulation. It is important at such periods that patients should be warned of the danger of the development of gastric ulcer and given precise directions how to avoid the local irritation that must concur with the underlying condition for the production of the ulcer. Young anemic girls are prone to be lovers of candy and small sharp pieces are sometimes swallowed. A taste for spices and for pickles so frequent during anemic conditions leads to the ingestion of acids and local irritants, that are liable to injure the gastric mucous membrane in its state of lowered vitality. Cooks are especially apt to take superheated food, but all young women patients must be warned of the danger from this source. Seamstresses often lean for hours with some portion of a vibrating sewing machine touching their epigastrium. Anemic governesses as school teachers lean against desks, which when the stomach contains food may prove a sufficient cause to locally depress the already sluggish circulation in the stomach walls.

All of these patients must be told of the absolute necessity of never swallowing coarse or insufficiently masticated food. Bread crusts should be removed or chewed very thoroughly. Raw apples and other uncooked fruit or vegetables, even celery, should be chewed very carefully before swallowing, or avoided entirely. At no time should the patient be allowed to take a large meal.

Fatal perforation in cases of latent gastric ulcer occurs particularly in patients who, having missed a meal for some reason, with more than ordinary heartiness at the next one. In general, the advice should be given to eat five or six times during the day rather than to limit the eating to ordinary meal times with the danger of mechanically injurying the stomach.

A PSYCHOPATHIC HOSPITAL FOR NEW YORK CITY.

WITH increasing wealth, science, like an ambitious housewife, is continually treating former luxuries as necessities; and is attended by a host of servitors who evolve new conveniences to meet new needs. This is inevitable with progressive civilization; in fact, is a sign of it; and a mistaken thrift that would keep to old or inconvenient methods is a false and provincial economy. And yet, with every new cry of the city for some much-needed improvement in matters of health, science or reform, the taxpayer fancies he hears the voice of the politician clamoring loudly for the people's good, and knowing well that voice, he concludes, in his despair, that some unnecessary extravagance is being foisted on the public for the private ends of a certain few.

But there is a distinct need in the city of New York that has not yet been voiced by politicians. It is a need that physicians and thousands of afflicted families have felt for years, namely, a receiving hospital for the diagnosis, treatment and clinical study of the acute insane. A city of the population and scientific attainment of New York ought to have a psychopathic hospital: and should not depend upon the inadequate and conglomerate system of receiving and caring for the acute insane that exists at present.

As long as Bloomingdale was situated in New York city, any patient of means could be taken there, others who had to be placed under confinement were taken to Bellevue until a diagnosis was made, and it was decided where they should be sent. Since the removal of Bloomingdale to White Plains, there is no choice but Bellevue.

The general popular prejudice against this hospital, combined with the recent revelations connected with its management, has made the city officers think seriously of transferring the function of detaining and examining insane patients to the Manhattan State Hospital. Commissioner Keller approves of this move, but adds that the medical students in the medical colleges connected with Bellevue would lose the opportunity they have now for studying insanity.

Such a move would, however, be but an inconvenient makeshift. It would dissipate rather than concentrate energy. It would add nothing to the usefulness of the State as the guardian of the insane.

On the other hand, a psychopathic hospital, centrally located, would serve for rich and poor without stigma. It would serve as a center for students; and would at the same time offer the widest opportunity for research work. The notable gaps in our knowledge relative to mental diseases have been for the most part unavoidable; students of clinical psychiatry have not had the opportunity to do research pathological work, and often pathologists' interpretations of cellular lesions are inadequately if at all correlated with the clinical diseased conditions.

In the foundation of the Pathological Institute it was hoped that this gap could be bridged, but experience has shown that what is needed in order to complete the idea is the establishment of a small reception hospital for the acute insane.

Such a hospital should be situated in the center of the city. It should be under trustee management. It should have a special training school for nurses for the care of the insane. It should be open for clinical advantages to all the regular medical schools of the city. It should be free to all the poor, and provide suitable rooms for any private patient who may be suffering from any form of nervous or mental disease.

Some thousands of patients, according to the city's experience with the receiving pavilion at Bellevue, would pass through such a hospital in the course of the year. These patients, instead of being merely objects of the city's charity, would receive the best treatment that the science of the city would command, and in turn would contribute directly to the students and neurologists of New York an opportunity to study the aspects of all forms of mental disease from every aspect.

THE DOCTOR AS A HUMORIST.

The spirit of science has ever seemed a somber goddess, enforcing the mask of the tragic muse on her votaries and making of her cult a sad-voiced worship to be performed only in the dust and ashes of mirthless labor, while the pursuit of the abstractions wherein she delights is considered but a descent into an all-enfolding Avernus where all laughter, as well as hope, must be left behind. And, of all the throng which follows in the train of the austere goddess and lay prosy garlands at her shrine, our Teutonic colleagues are supposed to be the ones most lost to the saving grace of humor and to tread the thorny path with the sternest footstep. But the average German medical contribution, with its encyclopedic sentences in which the thought vermiculates painfully through a tangle of many-jointed compound words, and starched to such a degree of purely objective stiffness as to seem almost machine-made in its rigid suppression of the ego, gives but an imperfect and usually wholly unjust impression of the writer. He is in truth but indifferently represented by the crabbed figure we see reflected on the ungraceful pages of his manuscript, and those of us who have met him on his native heath and had pleasing intercourse with him, seated in the garden of his pretty country-house and over varying metric quantities of his national beverage, have known him as a very affable and jovial comrade with his erudition tempered by good nature and fully ready and able to spice his life with all the Attic salt available.

The annual burlesque number of that most staid and dignified of weeklies, the *Münchener medicinische Wochenschrift*, gives pleasing evi-

dence that its distinguished editors and contributors are after all but human and the last issue is especially full of delightful nonsense.

A contribution from Dr. Swindel, of the Mississippi College, details the matchless benefits to be derived from the use of the author's "Grosshirnerholungsschraube," a slender screw-like instrument which is introduced into the base of the brain between atlas and axis. A few revolutions of the handle suffice to tighten the relaxed pyramidal fibers of the neurasthenic or brain-worker, thereby vastly increasing his motor power and capacity for outdoor exercise, while at the same time the association tracts are loosened and the cerebrum is short-circuited and given the opportunity for a much-needed functional rest.

In another masterly essay the psychopathology of Wagner's characters is discussed and the vagaries of each one fully explained by some plausible diagnosis of the alienist. Tannhäuser had circulatory insanity; Lohengrin, katatonia; Tristan gives unmistakable evidence of dementia praecox; Wotan's delusions of grandeur, with his failure to keep promises and other moral lapses, afford the classical picture of a middle-aged gentleman with beginning general paralysis, while the hapless Siegfried, with his unfortunate family history, is nothing but the victim of heredity and well-pronounced hebephrenia. An interesting bit of medical history is given in the reproduction of some of the quaintly-worded aphorisms of Mittelhäuser, an enterprising gynecologist of the sixteenth century who divides operative work in his specialty into three classes. The first comprises cases in which there is real disease of the pelvic viscera and an operation is followed by good results. This is but inferior workmanship and is often done by the least intelligent of practitioners. Then there are patients who have some slight trouble which might be relieved by conservative measures, but if the physician insists on removing uterus and adnexa it at once places him on a much higher plane of skill. And, finally, those are masters of the art, true favorites of Hippocrates, who have reached such a vanishing point of dexterity as to make a clean sweep of the pelvic contents even when there is absolutely no disorder whatever!

The proceedings of the Medical Congress of 2001 consider the grave question of how the sufferings of the profession from overwork are to be relieved, for, although each physician is now a Crœsus, what avails his wealth if the deluge of patients allows him no leisure to enjoy it? The remedy is simple, since the whole of treatment is reduced to wet packs and organotherapy, a three-months-course of study is sufficient to acquire proficiency, and the ability to write one's name is all the preliminary education needed. The Paris letter announces the discovery of a new organ extract, "piscilinguin," obtained from the tongues of fishes and intended to restrain unbearable loquacity in the gentler sex, while there is also an account of the localization of the prescribing center. By experiments on one hundred physicians it was shown that prescribing was a purely reflex act, stimulation of centripetal fibers for hysteria, for example, always causing the hand to write "Tr. Valerian," and that it could be performed entirely without the aid of the cortex.

Finally, there is a poetic effusion which celebrates in well-rounded strophes the invention of the enema in early Egypt, the somewhat Rabelaisian nature of the subject being condoned by the cleverness with which it is handled. Even the pseudo-advertisements are full of fun and the whole effect is to give a very pleasing impression of Jack at play.

ECHOES AND NEWS.

NEW YORK.

New York Academy of Medicine.—On Thursday, January 3, 1901, Dr. W. H. Thomson, the retiring President, gave an address. This was followed by the address of the incoming President, Dr. Robert T. Weir.

Appointment of Dr. Weeks.—Dr. John E. Weeks, University of Michigan, '81, has been appointed to the professorship of ophthalmology in the New York University and Bellevue Hospital Medical College, made vacant by the death of Dr. Henry D. Noyes. Dr. Weeks has been a lecturer in the medical school for the past two years.

Hebrew Sheltering Guardian Society.—This very worthy charity has just issued an appeal for $350,000 for the construction and maintenance of new buildings for neglected, destitute and orphaned Jewish children.

A Study of Cinchona.—At the regular meeting of the New York College of Pharmacy, 115 West 68th street, to be held Tuesday evening, January 15th, the subject of "The Cinchona Barks of the New York Market" will be presented by Mr. J. H. Stallman, and discussed by Mr. Albert Plaut and others. Mr. Stallman will illustrate his remarks by an elaborate series of specimens, and the College collections of barks

and herbarium specimens will be exhibited by Dr. H. H. Rusby, the entire series of specimens constituting probably the most extensive cinchona collection ever brought together in this country.

Obituary.—Dr. Isaac Warde Ferris died last week at his home in Mount Vernon from heart disease. Dr. Ferris was sixty years of age. He was born in New York city. He was graduated from the University of the City of New York, of which his father, Isaac Ferris, was chancellor from 1856 to 1869. Dr. Ferris practised medicine in Grand Rapids, Mich., and Schenectady, N. Y., and went to Mount Vernon twelve years ago. He is survived by a widow, who was Miss Cornelia S. Danforth, a sister of Elliott Danforth, and two daughters.

Charitable Bequests.—By the will of the late Henry Villard the following medical charities were benefited: The New York Infirmary for Women and Children, $10,000; The Charity Organization Society, $2,500; The State Charities Aid Association, $2,500; The New York Society for the Prevention of Cruelty to Children, $2,500; The New York Medical College and Hospital for Women, $5,000; The German Hospital and Dispensary, $10,000; The Dobbs Ferry Hospital Association of Dobbs Ferry, N. Y., $5,000. Both Columbia and Harvard Universities will receive $50,000, unrestricted.

General Vaccination in Brooklyn Schools.—In view of the growing fear of smallpox in Brooklyn, the Committee on Health of the local School Board, with the sanction of the Board, to-day notified the principals of the public schools that there was urgent necessity of careful examination of the records of pupils in regard to vaccination, and called upon them to notify parents of pupils whose records were not satisfactory that unless the State law was at once complied with, these pupils would be dismissed from the schools.

Office Thieves.—Two well-dressed men were being sought by the police of Brooklyn last week for robbing doctors. The men called at the office of Dr. Lorenzo M. Nickerson at Berry and South Ninth Streets, and when they were told that the physician was not at home they said they would await his return. They disappeared later and Dr. Nickerson discovered that a case of surgical instruments was missing. From the house of Dr. E. M. Bullwinkle at 85 South Ninth Street the thieves stole an overcoat. They also called at the home of Dr. Lottie A. Cort at 89 Division Avenue, but got nothing. Later they appeared at the house of Dr. William McLonathin, in Division Avenue near Berry Street, of Dr. Charles Zellhoefle at South Fourth Street and Driggs Avenue and at the office of Dr. Silas Blaisdell in Roebling Street. Each of these doctors was at home and the men asked for advice in connection with the supposed illnes of the wife of one of them and went away.

Lunacy Commission Economies.—As a result of the year's operations the State Commission in Lunacy reports a further reduction in the cost of maintaining the insane, in the face of a marked advance in the price of nearly every article entering into provisions and stores account. A thorough investigation has been made by the Commission of the pay-rolls of the New York State hospitals, and a marked reduction was effected in the salaries and wages of officers and employees. The average cost of maintaining the insane during the year just closed was $165 (inclusive of every item—salaries, wages, provisions, medicines, fuel and light, etc.), as against $178.42 for the preceding year. Building operations were conducted on a vast scale during the year on Long Island and on Ward's Island for the accommodation of patients of the Manhattan State Hospital. Further experimental studies have been prosecuted by Professor Atwater, the Government food expert, with a view to a more nutritious and at the same time more economical dieting for the insane of New York.

Bellevue Changes.—Commissioner Keller discharged seventeen employees of Bellevue Hospital last week. Their discharge, it is said, however, had nothing to do with the present investigation into the affairs of that institution. The reason given for all of the dismissals is insufficiency of appropriations.

Notices were sent out last Monday for a meeting of the Medical Board of the hospital on Wednesday. Drs. Fitch and Wildman, and Moore and others will present reports on the recent troubles. One of the cases which the Board has been asked to report on is that of Luther E. Newport, the wealthy patient in the insane ward who was committed to Amityville, and from whose relatives certain physicians are alleged to have collected $200 in fees when only $25 was allowed. Dr. Fitch and Dr. Austin Flint are both preparing reports to the Medical Board on the case. Dr. Flint said that his report would cover his entire connection with the hospital. By courtesy, he said, members of the Medical Board were allowed to visit private patients in the insane ward and their examinations were not under the control of the department. They were the same as though the patient was in a private institution, he said. Mr. Keller is prepared to fight the Medical Board if necessary. He said that the Board was subject to his orders in the investigation and must answer his questions. "I have demanded an explanation," said he, "and I will get it. I have reprimanded Drs. Fitch, Wildman and Moore for their administration of affairs in the insane ward and I have asked an explanation from Dr. Fitch for collecting excessive fees from patients. If these physicians are

wrong things will be made right, but the guilty men will have to take care of themselves."

Cornell Medical College Opening.—The exercises formally opening the new Cornell University Medical College building which has been in use since last August, were held in the main lecture hall of the building last week. Speeches were made by Governor Roosevelt, President Seth Low of Columbia University, Dr. Lewis A. Stimson, and Jacob G. Schurman, President of the University.

President Schurman said in part: "We meet together to dedicate this new building committed to our charge for the relief of man's estate in the twentieth century and the countless ones to follow. The object of this building and the aim of this college is the protection of human health. This institution is devoted to investigation and instruction. While it is eminently a practical place, provision has also been made for carrying on scientific research. Besides building and scientific equipment, there is something else of vastly more importance, and that is the men whose intelligence and capability determine the worth of any institution."

President Schurman then introduced Dr. Lewis A. Stimson, who read a paper detailing the aims and purposes of the school, and following Dr. Stimson introduced the Governor, who said: "I shall not attempt to add anything to what Dr. Stimson has said so well. But I wish to ask your attention to the need of having in the community men who will do as Colonel Payne has done, and of the duty which rests on men of Colonel Payne's kind to act in that manner. There is need, as Dr. Stimson showed, of a State having an opportunity open for men to do work which is of the utmost importance, but which must be done without pay, or, at most, paid for far out of proportion to its value. It would not be saying too much to say that the men who made the America of which we are so proud to-day were absurdly paid from a financial standpoint. Men in different walks of life, the great inventors, artists, statesmen, mechanics, electricians, scholars, lawyers, physicians, are almost always men whose reward has been the work itself. From the time when Milton sold one of the three greatest epic poems the genius of mankind has produced for $5 down to the present time, the best work has almost always been work for which remuneration could not have been given. There must be a recognition of the need for such work or there will be a failure on our part to provide those conditions under which such work can be carried on. To a certain extent these conditions can be furnished by the State, but it is questionable how far the State's jurisdiction in such matters shall extend. But no matter how much the State may do, no act by it can supplant the action of private individuals. In their initiative we must look for the initiative which will enable the research work of the world to be accomplished. Action by State and individual must go hand in hand.

"I think that no small amount of praise is due Colonel Payne for the right he has given others to use his gift without restraint or condition. It is an eminent instance of good American citizenship, both in what he has done and in how he has done it. We must remember that the necessity of unremunerative work also imposes as well the need of having remunerative work done. You cannot expect the laboratory to be built and maintained unless a portion of the wealth made in the great channels of business is set aside for their maintenance. We owe a great debt to the scientific man unquestionably, but we owe an incalculable debt to the man of affairs who has foresight and breadth of mind to see the necessity of providing means by which such work can be prosecuted. I feel that we should be congratulated ourselves as residents of a community with so many grave problems confronting it, upon having such a distinct addition to the forces which must war interminably for right against the forces which war for wrong."

President Low of Columbia said: "It's a great pleasure to welcome a younger colleague in the fight which education is waging against ignorance. Columbia rejoices in this new gift equally with Cornell; for no matter what university receives a gift every other university benefits equally from it. The higher the standard Cornell maintains the higher Columbia is bound to be for it, and vice versa. If men start out to gain there may well be some jealousy, but if they start out to give, one can only emulate the other. So the oldest medical faculty in this State congratulates the youngest on the magnificent equipment it has received, and rejoices with it."

Dr. Polk then made a few remarks and the exercises closed. In the evening a reception was held in the building from 8 until 11 o'clock.

Brooklyn Neurological Society.—At the annual meeting of the Brooklyn Society for Neurology, held December 27, 1900, Dr. W. H. Haynes was elected president and Dr. B. Onuf secretary for the year 1901.

PHILADELPHIA.

Section on Ophthalmology, College of Physicians.—At the meeting of December 18, 1900, Dr. G. C. Harlan showed a patient with myosis and ptosis, due to a gunshot injury of the right cervical sympathetic received five years ago. The right pupil responded promptly to light, but was 2 mm. smaller than the left either in contraction or dilatation. There were no other symptoms and no history of unilateral sweating. Dr. James Thorington exhibited a boy, fourteen years old, with subluxation downward and inward of each lens. Dr. C. A. Veasey reported a case of restoration of useful vision in a complicated case of acute inflammatory glaucoma of ten days' duration, with visual acuity reduced to

the perception of light. Dr. H. F. Hansell reported a case of tuberculosis of the conjunctiva in a healthy child thirteen years of age. The diagnosis was based upon the microscopic examination made by Dr. E. A. Shumway that demonstrated a central area of necrotic tissue surrounded by mononuclear cells and by cells of an epithelioid type, with many giant-cells. Dr. W. M. Sweet exhibited a piece of iron imbedded in inflammatory exudate removed from the vitreous by forceps after failure of magnet.

The Case of Insane Criminals.—What was feared might prove to be another hospital scandal has been cleared up by the Coroner's jury in the case of Frank Hodges, a colored inmate of the State Hospital for the Insane at Norristown. Hodges died December 26th, ten hours after an encounter with three of his attendants, several of his ribs having been broken during the struggle. The inquest brought out the fact that Hodges was a homicidal maniac and had made previous attacks upon fellow-inmates and attendants. The verdict of the jury was that Hodges died from organic troubles (heart and kidney disease), his death being hastened by the struggle with his attendants in their efforts to restrain him from injuring himself and others. The hospital authorities and attendants are exonerated from all blame. The verdict closes as follows: "We recommend that the proper authorities establish a place for the treatment of the criminally insane as their presence here is a menace to the lives of both patients and attendants." The hospital staff strongly endorses this recommendation. There are now about fifty criminally insane patients in the institution, the facilities of which do not allow of their proper and safe keeping.

Nervous System in Rabies.—At the Pathological Society December 27th, Dr. D. J. McCarthy gave the results of postmortem findings in a number of cases of rabies. The cases included dogs, horses, etc., and one human being. In the medulla and pons there was found cavity formation resembling pseudoporencephalia. The tissue surrounding these cavities, however, showed no evidence of inflammatory reaction. This, together with other facts, proved the cavity formation to be a postmortem change. In some of the cases large bacilli were found, but the variety could not be demonstrated. Dr. Wm. G. Spiller stated that the lesions found in rabies may also occur in other diseases, as acute ascending paralysis. These lesions are probably the result of general irritation or proliferation. Dr. Spiller concludes that there are no lesions of the nervous system specific to rabies.

Scurvy, not Rheumatism.—Dr. J. P. Crozer Griffith read a paper on the above subject at the County Medical Society December 26th, reporting 16 cases of infantile scurvy. The cause of scurvy is a dietetic one, but with our present knowledge no one dietetic error can be blamed. Proprietary foods are the cause in some instances, one of the 16 cases reported having recovered when such food was stopped. In Dr. Griffith's experience sterilized milk is not a factor in the production of scurvy, no noticeable harm having come from its use. The heating of milk, therefore, should not be hastily abandoned in such cases if there be any reason which makes its continuance desirable. The disease is preeminently one that affects the children of well-to-do persons, there not being a child among the 16 cases reported which had not been carefully cared for. Rheumatism is the diagnosis most frequently made when a case of scurvy is not recognized as such. This is due to the fact that a spongy condition of the gums is not the symptom first noticed in the majority of cases. Instead of this there is pain in the legs. Indefinite pain in the legs should be regarded as presumptive evidence of the existence of scurvy. Aiding in the differential diagnosis is the fact that the pain associated with scurvy is not felt in the joints. The therapeutic or the dietetic test is generally sufficient. The test by the use of the salicylates is not always reliable, one case of scurvy having improved for a time under the administration of salicylate of strontium, though entire recovery did not take place. The use of orange juice is a better test. The treatment of scurvy is most simple and consists principally in the exhibition of fruit juices. Several cases recovered under this treatment, although the regular diet was not changed in the least. Dr. H. A. Hare, in speaking of the diagnosis, mentioned one case of scurvy in which excessive tenderness of the spine was the only symptom. In another case the child kept up an incessant screaming. A notable point in the latter case was that it was a breast-fed child. In a third case the parents were wealthy and had purchased a high-priced Jersey cow to ensure a pure milk supply for the child. Dr. Hare states that scurvy is more frequently found among the richer classes of people, while rickets is a disease of the poor.

CHICAGO.

Chicago Medical Society.—At a meeting, held December 26th, Dr. Daniel H. Williams read an interesting paper on "Ovarian Cysts in Colored Women," and presented notes with regard to the relative frequency of fibromata in both races. Dr. E. A. Fischkin reported a case of an eruption which resembled pemphigus vegetans in an infant five months old.

Obituary.—Dr. Randolph N. Hall, for twenty years a practising physician, dropped dead Sunday, December 30th, shortly after his return from church. Apoplexy was said to be the cause of death. He was a native of Ohio, and a veteran of the Civil War. After the war he studied medicine at Rush Medical College and other Chicago medical colleges. He was president of the Illinois Medical College when it was founded and a member of various medical associations.

Committee on Medical Legislation of the Illinois State Medical Society.—This Committee has been endeavoring during the past five months to find out what the profession of Illinois considered desirable legislation. It has been discovered that the irregulars are making every effort to organize their ilk for the introduction of vicious legislation and the defeat of existing legislation. After having canvassed the matter thoroughly, the Committee believes that there are a few things on which the profession is fairly well agreed, and that the best plan for the present is to league together as many of the doctors of the State as possible. The objects should be: (1) To secure the appointment of the best men for the various medical positions in the State, when a vacancy occurs. This work is more particularly in charge of the Judicial Council of the State Society. (2) To prevent vicious legislation which will undoubtedly be proposed at the next session of the Legislature. (3) To secure the enactment of better sanitary and health laws. There is especial need for organization of a permanent league for the promotion of the material interests of the profession, and to give support to all desirable sanitary and health measures. One of the first duties of such a league would be to protect the members of the profession against unjust suits for malpractice. Organization will accomplish what any amount of individual effort will fail in. Those who become members of the league, who are not members of the Illinois State Medical Society, will be kept constantly informed of the various plans devised for preventing vicious legislation and securing that which is desirable as well as perfecting plans for a permanent organization.

Hospital Internes.—Physicians appeared recently before the service committee of the County Board and argued for the present system of appointing internes. The resolution of Commissioner Organ was denounced, and a substitute resolution was submitted by Dr. Denslow Lewis, which asked for the assignment of patients to the three medical staffs on duty at the hospital in accordance with the number of students now in attendance at the medical colleges in this county. The present attendance is: Eclectic, 101; homeopathic, 659, and regular, 2,648. This gives the following ratio for the assignment of patients: One to the eclectic, 6 to the homeopathic, and 26 to the regular. No final action was taken by the Committee, but the physicians were asked to express themselves, which they did, and a majority of them present stated that the system now in vogue was satisfactory.

West Side Hospital Training School for Nurses.—An institution bearing this name was recently incorporated by Drs. D. A. K. Steele, William L. Noble and George W. Newton.

Western Surgical and Gynecological Association.—At its meeting, held at Minneapolis, December 27th and 28th, the following officers were elected for the ensuing year: President, Dr. A. F. Jonas, Omaha, Neb.; Vice-Presidents, Dr. A. W. Abbott, Minneapolis, and Dr. C. E. Ruth, Keokuk, Ia.; Secretary-Treasurer, Dr. George H. Simmons, Chicago; Executive Council, Dr. O. B. Campbell, St. Joseph, Mo.; Dr. H. C. Crowell, Kansas City, Mo.; Dr. John P. Lord, Omaha, Neb.; Dr. James E. Moore, Minneapolis, Minn., and Dr. M. L. Harris, Chicago, Ill. Chicago was selected as the place for holding the next annual meeting.

Detailed to the Pan-American Congress.—Major Walter Reed, Surgeon, has been detailed to represent the Medical Department of the Army at the Pan-American Medical Congress which is to meet in Havana on February 5th.

Yellow Fever and the Soldiers.—Acting on the recommendations of the Board of Officers Governor General Wood has issued an order in Havana which declares that the chief surgeon of the Department of Cuba has reported that it is now believed to be well established that malaria, yellow fever and filarial infection are transmitted by the bites of mosquitoes. The troops are enjoined to observe carefully two precautions: First, they are to use mosquito bars in all barracks, hospitals and on field service whenever practicable; second, they are to destroy the "wigglers" or young mosquitoes by the use of petroleum on the waters where they breed Permanent pools or puddles are to be filled up. To the others are to be applied one ounce of kerosene to each fifteen square feet of water, twice a month, which will destroy not only the young, but the old mosquitoes. This does not injure drinking water if drawn from below and not dipped out. Protection is thus secured, according to the order, because the mosquito does not fly far, seeks shelter when the wind blows and that each community breeds its own mosquitoes.

Mad Dogs in Rochester.—According to press despatches, rabies has been declared epidemic in the city of Rochester by Health Officer Goler and Mayor Carnahan has ordered that all dogs be muzzled. This is the announcement to the Mayor by Health Officer Goler:

To the Hon. George A. Carnahan, Mayor:

Sir: In response to your request I have the honor to report that rabies has become epidemic among dogs in the city of Rochester. Between about June 1st, and the present date I have seen somewhere between twenty-five and fifty dogs with unmistakable evidences of rabies. A number of these dogs have proved rabid by inoculating other animals, chiefly rabbits. And in four cases the work of this department has been corroborated by Prof. V. A. Moore of Cornell University and

by M. B. Ravenel of the University of Pennsylvania. As rabies is a disease having long period of incubation, in dogs from 10 to 240 days, it appears necessary that stringent measures should be taken for the protection of the public against the bites of animals, either those known to be rabid or even bites given in play, as it has been experimentally proved in a number of cases that a dog may be capable of transmitting rabies before the animal has itself developed the disease which lies dormant in it. I have, therefore, the honor to recommend as most necessary at this time the promulgation of an ordinance which shall not only compel all dogs to be muzzled with a basket muzzle, but shall also require that all dogs shall be led.

Such an ordinance appears most urgent, because rabies in animals has such a long period of incubation and because the disease appears not in the furious but in the milder and therefore the more dangerous form, the dogs often appearing to have what is known technically as "mouth drop;" that is, the dog being unable to close its mouth and having but a slight paralysis of the hind-quarters. This mild form of the disease is more dangerous than the furious form, because it is not generally recognized and the dog is often believed to have distemper or some other dog disease when it really has the most dangerous form of the disease known. For these reasons, and for the further reason that no authentic case of recovery from the disease after it has once developed in man has ever, to my knowledge, been reported, I have the honor to submit these recommendations. Respectfully,

George W. Goler, Health Officer.

The Mayor's official order regarding the muzzling of dogs follows: "It appearing to me from the reports of the Health Officer of the city of Rochester, that it is necessary that the precautionary measures be taken against the spread among dogs of the disease known as 'rabies;' now, therefore, pursuant to Section 12 of 'an ordinance relating to public pounds and stray animals,' passed by the Common Council of said city on the 11th day of May, 1897, it is ordered: That, until further notice, the owners of dogs are prohibited from allowing them to run at large in any public street or place within the city of Rochester, unless such dogs be securely muzzled or led by a line or chain so as effectively to prevent them from biting any person or animal.

"George A. Carnahan, Mayor."

Rochester, Dec. 28.

Accompanying the letter from Dr. Goler to the Mayor, were copies of letters received from Professor Moore of Cornell University and Dr. Ravenel of the University of Pennsylvania, stating that they had made tests with the brains of dogs and horses sent them by Dr. Goler and had proved beyond doubt in their minds that the animals from which the brains were taken died of rabies. The histological changes found were those characteristic of this condition

CORRESPONDENCE

A WORD FROM DR. GOULD.

To the Editor of the Medical News:

Dear Sir: Although the rumor had for some time been current that a change in the editorial management of the Philadelphia Medical Journal had been planned, to take place synchronously with the obtaining of a controlling interest in the concern by a lay newspaper publisher of this city, the thing seemed so absurd that I did not give it credence, until I received sure information from a private hand that such action was contemplated, a meeting being called so late on Monday afternoon as to afford not an hour's notice. This reached me just as the forms had gone to press on Friday evening. Thinking it merely just to my friends among the subscribers that I should say a word of farewell, and not dreaming that such opportunity would be refused to me, I inserted the following editorial with two others. They were removed.

"Just as the last forms are going to press I learn that the present number of the Philadelphia Medical Journal will be the last (except as to the original article department of the next issue) for which I shall have editorial responsibility. I am unable to set forth the reasons why the Board of Trustees no longer wish my services as editor. I have not heard of any criticism upon their part of my conduct of the Journal, and my communication handed to the Board in session on December 8th, expressing my desire to be retained as editor, has not been answered.

"To the thousands of friends, to all subscribers, who may read these lines, I can only here express my most profound regret at the sudden separation. In the endeavor to aid in establishing a great independent medical journal, utterly free from publishers' influence, from commercial bias, and from what is, if possible, still worse, an unprofessional spirit within the profession, I have given my labor and my life, all too freely. What mistakes I may have made I trust may be excused in the belief that they were due to a sincere desire to devote every line of the reading columns to the cause of professional truth and honor."

The essence of the matter lies in the above, although it may be added that the only conflict of which I am aware was upon the question of editorial independence, this even having reached the extent of the establishing of a lay censorship during my absence last summer. Although this was abrogated upon my return, I suppose the effort must have been continuous, leading necessarily to the selection of someone likely to prove more compliant to act as editor. There are other points of interest, which take too much space to explain. But the first official intimation that my services would no longer be required reached me at 6 o'clock on Monday, and the editorial pages of the Journal, as they appeared when the issue of the 29th was finally published, were censored during my incumbency as editor.

George M. Gould.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, December 22, 1900.

THE OUTBREAK OF ARSENICAL POISONING FROM POISONED BEER—ABOUT TWO THOUSAND CASES IN MANCHESTER ALONE—ALLEGED DEATHS FROM PERIPHERAL NEURITIS—CASES IN LIVERPOOL—ARSENIC DISCOVERED IN THE URINE—RECOVERY OF AN INFANT AFTER FOURTEEN AND ONE-HALF HOURS' ARTIFICIAL RESPIRATION—DEATH OF DR. RICHARD NEALE, AUTHOR OF THE "MEDICAL DIGEST"—THE INQUIRY INTO THE MANAGEMENT OF THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC—ANTI-VACCINATORS IN CONGRESS.

THE OUTBREAK of arsenical poisoning in Manchester and vicinity, from poisoned beer, is the center of public attention, and has given rise to scares all over the country as to the purity of beer. Rumors are constantly arising of cases of poisoning and a number of deaths have been recorded as actually or possibly due to arsenic in beer. The whole subject is now engaging the attention of the government, and experts are at work on the investigation. I think it best not to trouble you with the different sensational reports which have not been verified, but will speak of ascertained facts. Dr. Niven, Medical Officer of Health for Manchester, in a report to the Sanitary Committee, says it may be assumed that there have been about 2,000 cases of poisoning from beer containing arsenic. He examined samples of sugar and saccharine from six local breweries, and found arsenic in them all.

Sir Lauder Brunton, Dr. Stevenson, Dr. Luff and others have been appointed by the Manchester Brewers' Association to inquire into the presence of arsenic in beer. As the result of a week's investigation, they have issued an interim report. They conclude that the materials in current use in brewing in Manchester are free from arsenic, with the exception of certain sugars supplied by Messrs. Bostock & Co., of Liverpool. In appearance and price these sugars are indistinguishable from perfectly pure sugars. They recommend that all beer in the brewing of which these sugars have been used should be at once recalled, and if found contaminated be destroyed. Also that no beer be sent out until it has been tested and found free from arsenic. A number of deaths from peripheral neuritis, alleged to be due to arsenic, have occurred. Inquests are now pending, so that it is premature to offer an opinion.

At Liverpool, four samples of beer were found contaminated with arsenic, one considerably. At Birmingham, arsenic was found in twenty out of one hundred and seventy samples. The number of cases of peripheral neuritis in Liverpool has been much less than in Manchester, but has lately been decidedly increased. They correspond rather to beri-beri than to arsenical poisoning as described in Manchester. When the discovery of arsenic in the beer of Manchester was made, the urine of one of the Liverpool patients was examined and found to contain arsenic. The superintendent of the Mill Road Infirmary states that during the last week nine cases were admitted to the infirmary. He rather naively remarks that the character of the cases has undergone a change, as the new admissions present more of the symptoms of arsenical than of alcoholic neuritis! One case gives an indication of the amount of beer necessary to produce the symptoms, and the time required: A man aged forty, who had been a teetotaler for six months, drank, on November 24, 25 and 26, thirty-six pints of beer. In forty-eight hours he was seized with burning pain in his face, ears, hands, and feet, edema of the eyelids, and running of the eyes. He had no vomiting, or diarrhea. Under treatment he was soon much improved. Arsenic was found in his urine on December 2 and 3, but not on December 4. One woman who had been in hospital for two weeks died from excessive beer drinking with arsenical symptoms. The Liverpool brewers have destroyed upward of 1,000 gallons of beer containing arsenic.

A very remarkable case in which an infant recovered after fourteen and one-half hours of artificial respiration is recorded in the *Lancet*, by Dr. G. E. Keith. The child was seven days old, and was prematurely born by three weeks. Circumcision was performed. He " did not breathe well under the chloroform, and lost more blood than usual." The operation was performed in the morning; during the night he became cyanosed, and soon respiration stopped, but the heart continued to beat. Artificial respiration was commenced, and after twenty minutes natural respiration was established, only to cease in a few minutes. Artificial respiration was recommenced. Soon the heart seemed about to fail, and the pulse dropped from 200 to 100. Hour after hour the doctor kept up the monotonous artificial respiration, becoming more and more convinced that he labored in vain. At noon a creak occurred, showing that the lungs were filling with fluid. The heart was again failing. A cylinder of oxygen was then available, and its use caused great improvement. The face lost its earthy hue, the moist sounds died away, and the heart beats increased in strength. At 3:30 p.m., twelve hours after the commencement of artificial respiration, a feeble inspiration took place, and at 5:45 natural respiration was established.

By the death of Dr. Richard Neale the profession has sustained a great loss. His life-work, the *Medical Digest*, at which he labored until the end, is invaluable to every member of the profession. As a student he commenced at the work by noting for his own use important points which appeared in the medical journals. When he began practice, in Java, he found these so useful that he decided to continue the work. Some fifty periodicals were used. They were all in the English language, and were principally British. The work included a record of the most important points in the journals. Thus perhaps to one article twenty or thirty references would be made. The labor involved may be imagined. At this work Dr. Neale labored four hours a day for fifty years. Successive editions of the *Digest* were brought out, and though the work was well appreciated, it was never remunerative. True,

in the closing days of his life a subscription list was opened in the medical journals to present him with a testimonial, which it was decided would take the form of a portrait of himself, and Dr. Neale was well pleased with this small and tardy recognition of his labors. As has been said, the great value of the work lies in its use to the busy practitioner. The author, the bibliomaniac, anxious to cover a page with references good, bad, and indifferent, in order to display his learning, will not find it of much use. But the practitioner who is always encountering anomalies and curious variations of disease, need never look in vain in the *Digest* for information on any point, and in cases in which ordinary treatment fails, will find scores of suggestions.

The Lord Chancellor, the Right Honorable Sir Ford Worth, has consented to conduct an inquiry into the allegations made by the medical staff of the National Hospital for the Paralyzed and Epileptic. On this matter I have already advised you. He will report on (*a*) the diet of the patients; (*b*) their condition, care, and treatment, and (*c*) the nursing. It is certainly time that the long standing complaints of the staff as to the management of this most important charity both from the scientific and the humanitarian standpoint, were thoroughly sifted.

The National Anti-Vaccination League have held their annual conference. Like every other "anti-" body in this country the league receives a good deal of support from a number of important people whose intellectual caliber is by no means deficient. The president of the league, Lieutenant-General Phelps said that there were now 3,000,000 children under the age of fourteen in England, who were not vaccinated. He ridiculed the "Conscience Clause" of the recent Vaccination Act, which virtually abolishes compulsion by allowing exemption from vaccination on the parents of a child making a declaration before a magistrate that they have a "conscientious objection" to vaccination. Mr. Hopwood, Q.C., the recorder, of Liverpool, declared that the statistics of the French and German armies in the war of 1870 which showed the great value of the thorough rules of vaccination of the Germans, were false. It is evident that nothing short of an epidemic of small-pox will convince a large section of Jenner's countrymen of the value of his discovery.

FIBROMA OF THE TONGUE—CARCINOMA OF A SUPERNUMERARY NIPPLE—PSEUDO-ACTINOMYCOSIS—CLEIDOTOMY—APHASIA—ABSCESS OF THE SCALP—RACHITIS AND TUBERCULOSIS—VESICAL OPERATIONS—UNDESCRIBED URINARY CRYSTALS—TRANSVERSE SUPERFICIAL PERINEAL INCISIONS—THROMBOSIS OF THE ASCENDING CAVA, COMMON AND EXTERNAL ILIAC VEINS SIMULATING PERFORATED GASTRIC ULCER—SPLENECTOMY—INTERMITTENT ESSENTIAL FEVER OF SYPHILIS.

W. G. Spencer, at the Pathological Society of London, November 20, 1900, exhibited a specimen of fibroma of the tongue, removed with a portion of the organ on the diagnosis of carcinoma, because it was ulcerated and extended into the muscular substance. Its site was ventral and mesial, suggesting an origin from the remains of a fetal structure representing the glossohyal element present in certain mammalia and in the tongue of the chameleon. This element is bony in the horse, cartilaginous in the dog, and portions of both bone and cartilage have been found in the fetus in its site and explicable only on these grounds.

The same author presented a specimen of carcinoma arising in a supernumerary nipple, sypheroidal-celled, ulcerated, without secondary disease of the axillary glands, histologically of the type of rodent ulcer.

In the neighborhood of this was a second mole, pigmented, covered with unaltered epidermis, filled with structures like sweat ducts, without malignant characters, but probably readily convertible to a carcinoma, as had occurred in the first one. Rodent ulcers in birth marks and moles have been recorded by others. The cutaneous glands enlarging in pregnancy are of the class of sweat glands.

Dr. Habershon and P. S. Hichens presented a case of pseudo-actinomycosis. The history is: Errand boy, seventeen years old, admitted to the Brompton Hospital November, 1897, with cough, expectoration, pain in the right chest, dulness over the lower half of the right lung, feeble tubular breathing, and slight hepatic enlargement. His temperature ran from 101° F. to 102.4° F., with occasional fluctuations. The sputum increased in amount without traces of tubercle or other organisms. A collar button was suddenly coughed up, in December, with a large amount of sputum. This was followed by so much improvement in all the symptoms that the button in bronchus was assumed to be the cause of all the trouble. In three weeks the signs began to increase slowly, and in four weeks more an abscess developed in the right nipple line over the sixth rib, the temperature showed diurnal fluctuation and at the end of February, 1898, the abscess was incised and some pus escaped. The discharge increased and became offensive. The fluctuation of temperature increased, following an intermittent, and finally a remittent type. Hepatic dulness increased. Several exploratory operations failed to discover any focus of pus, or to relieve the patient. Progressive prostration, jaundice, and successive rigors developed, and death in May, 1898.

The necropsy revealed an old collapse and induration of the base of the right lung; extensive cheesy infiltration of the right lobe of the liver extending into the left lobe, with many softened, pus-filled cavities, but without true honey-combing; the capsule of the liver beneath the diaphragm, was covered with a caseous layer partly adherent to the diaphragm, forming mul-

tiple abscesses, and one suppurating tract communicating with the external wound. The pus contained small granules, in size resembling those of actinomyces, but in color differing by being of pale or cream yellow, and by being very friable. Weigert's modification of Gram's stain revealed a mycelium composed of delicate streptococcus—like threads, though one series presented most delicate filaments; all smaller in size than the normal actinomycotic mycelium and more abundant in sporulation, some apparently consisting of nothing but strings of cocci. Stained bodies from the caseous area about the liver showed concentric rings similar to those in actinomyces, under low power. High magnification showed multitudes of very small cocci with many delicate threads in streptothrix form, with no evidence of dichotomy. Allusion to the literature on the subject was made, especially to the anomalous actinomycosis called oösporon asteroides and bacillary actinomycosis. This case appeard to differ essentially from these, and from the true disease. The absence of the clubs does not appear important, because in the human subject they are often absent. Perhaps this is another form of streptothrix presenting clinical and pathological similarities with the ordinary actinomycosis. Habershon also showed another specimen of this disease, with scattered multiple abscesses all through the body and with secondary caseous hepatic degeneration.

J. W. BALLANTYNE, at the Edinburgh Obstetrical Society, November 14, 1900, reported a case of cleidotomy with the following history: The twenty-five-year-old primipara showed signs of rickets, contracted pelvis with three-inch conjugata vera diameters, and after twelve hours' labor the head at the brim in the left occipito position. The forceps were futile. Basilysis, then crushing of the base of the skull, had to be done. The head was then brought down to the perineum and partly through the vulva, where a fetus became impacted. The right clavicle was now divided with long, strong, blunt-pointed scizzors, and a blunt hook was passed through the left axilla. In this manner delivery was accomplished and a good recovery resulted. There are several other cases of cleidotomy, as an auxilliary of cephalotripsy, reported in literature. Other operations may be substituted for it. Cleidotripsy is inelegant and unsatisfactory; cleidorrhesis is difficult and uncertain. The force is applied to the shoulders, and may be used in breech cases when the most of the trunk has been born; supra-acromistomy is a good substitute when the clavicles can not be reached, and is available in severe cases like eclampsia, otherwise it is inexact. The technic of cleidotomy consists simply in passing the index of the middle fingers of the left hand over the thorax of the child, and then with the right hand advance the scizzors along these as guides and cut the bone at the desired point. Its indications are (1) a broad-shouldered fetus with head normal, enlarged or deformed; (2) an abnormal pelvis, contracted, rachitic, kyphotic, justo-minor; (3) a broad shouldered fetus in an abnormal pelvis, neither excessive; (4) impacted shoulders in breech cases; (5) threatening eclampsia or uterine rupture, or other cause for immediate delivery. In all these applications of cleidotomy it is usually a procedure secondary to destruction of the head, and carried out upon a dead child, although not absolutely essentially. As a substitute for indiscriminate embryulcia it serves an excellent purpose on account of ease, elegance and efficiency.

H. T. BEWLEY, at the Royal Academy of Medicine in Ireland, November 2, 1900, showed the brain of a thirty-three-year-old woman, who in May, 1897, suffered from an attack of apoplexy with unconsciousness, slight temporary paralysis of the lower right half of the face, and aphasia. The difficulty with the speech improved but never entirely disappeared. Nine months later, still aphasic, the patient died of tuberculosis of the lungs. At the autopsy an old hemorrhage was found near the left island of Reil, destroying the grey and some of the white matter of the convolutions of the insula. A small cavity occupied the place of these convolutions, and about it was much yellowish substance abundant in granules of hematoidin. The exact site of this hemorrhage appeared entirely bounded by the convolutions of the island of Reil.

A. C. O'SULLIVAN gave the bacteriological details of an abscess of the scalp involving the frontal, both parietal, and both temporal bones. streptococcus pyogenes and staphylococcus pyogenes albus and aureus were abundant. The streptococci were exceedingly virulent, as 1 c. c. of broth culture injected intraperitoneally into a rabbit and subcutaneously into a guinea pig caused death in about twelve hours. The staphylococci were innocuous in mice and guinea-pigs.

PROFESSOR BENNETT added that this same patient had shown a combination of rachitis, and disseminated tuberculosis, a clinical curiosity. The child suffered from early rickets, and when six or seven years old the tuberculosis supervened. Over the left temporal fossa had been a tuberculous abscess, like many others elsewhere in the body. He had the ordinary signs of a tuberculous meningitis in children. The question then came up whether the temporal abscess should not be evacuated and the dead bone, palpable though not detached, removed. If this had been done only a small piece of dead bone would have been found, and that was free of tubercles. PROFESSOR MCWEENEY said it was a pity, for the sake of diagnosis, that no animals had been inoculated directly from these abscesses. It is so difficult to recover the tubercle bacillus from all exudates and transudates, that he felt that animal inoculation is the surest diagnostic test.

T. R. Bradshaw (Liverpool), at the Royal Medical and Chirurgical Society of London, November 27, 1900, described the case of a man with dilatation of the stomach who had taken large quantities of magnesium carbonate. The urine was abundant in sediment, apparently not described, and in fine sheaf-like acicular crystals of monohydric magnesium phosphate.

T. Smith read a paper on the possibilities of improving the method of operating on the bladder for calculi and new growths. In view of the increased diminished risk of interference with the peritoneal cavity, he considered it possible, in selected cases, where the desideratum is the immediate union of the bladder wound, to make the operation intraperitoneal, and thereby avail one's self of the rapidity with which opposed layers of this serosa unite. C. Lucas said in the discussion that the bladder is so prone to be septic, in these conditions, and even to become so after the operation, that any intraperitoneal approach will be highly hazardous because the mucous, fibrous, and muscular elements of the bladder-wall will suffer less in degree and extent than the serous. Foyer considered the very ease and directness of suprapubic lithotomy its dangers, because the operation is often done when lateral lithotomy or lithopaxy would be more safe. Statistics give twenty per cent. mortality for the suprapubic route, and only five per cent. for each of the other means. One special danger in an intraperitoneal attack upon the bladder lies in the necessity for copious irrigation, which, in spite of caution, is very prone to wash septic matter into the peritoneal cavity. C. Heath pointed out that complete rest for the bladder, and open avenue for the direct application of medication, are gained by allowing the vesical incision to close by granulation. This fact alone would controvert the claims of the paper. A. Barker said the dangers of sepsis had been much exaggerated. A good preliminary treatment with irrigation would render the bladder quite clean, just as in the case of the stomach. Compared with the recent changes and advances in gastric surgery he felt that an intraperitoneal vesical operation is not only possible, but also wise in certain cases. W. G. Spencer quoted Milton, of Cairo, who opened a bladder in this way for a large stone. Death followed later from other causes. No adhesions were found at autopsy.

W. G. Spencer read a few notes on perineal urethrotomy and cystotomy through a superficial transverse incision, after the method of Celsus. The incision is convex anteriorly, extends from ischial tuberosity to tuberosity, and through the central point of the perineum, exposes both the arteries to the bulbous urethra and perineum (which are at once tied), and the external sphincter and rectum (which are freed and retracted backward away from the urethra bulb). The urethra is now carefully divided just in the mid-line, backward to the prostate, so that the neck of the bladder is reached without any tearing. Very rapid healing follows this procedure, urine passes by the penis in about two days, and ceases by the perineum in about seven days more. The edges of the wound tend to fall together when the legs are brought out of the lithotomy position. His cases included: (1) old urethral strictures which were widely divided mesially on the floor and roof, and the associated false passages were cleanly opened. Healing without fistula resulted, and the patients were taught to pass a large bougie themselves. (2) Calculi in contracted, hypertrophied, or sacculated bladders, unsuitable for suprapubic or lateral lithotomy were extracted freely in this way, and the cut urethra healed well, as no tearing was needed. (3) Lateral lobular prostatic enlargement, like a collar about the neck of the bladder, was easily cured by the cautery, or by actual excision. The preliminary ligation of the arteries kept the field clean and dry, retraction of the rectum protected it and enlarged the deep field, while a furrow cauterized in the prostate permitted good drainage of the postprostatic pouch.

S. Phillips, at the Clinical Society of London, November 23, 1900, gave prominence to the following rarity: Maid-servant, nineteen years old, prolonged indigestion, sudden onset of symptoms of perforated gastric ulcer, slight temporary improvement under hospital treatment, followed by signs of thrombosis of the deep veins of the left leg, with later edema of the whole lower extremity, rigors and death about nine days afterward. The post-mortem examination showed recent soft thrombosis of the ascending vena cava, left common and external iliac and the left lower extremity veins. Extension of the thrombosis upward to the heart had caused death. The clotting had begun in the vena cava, and had spread up and down. In nature it was apparently *primary infective thrombosis*. Its initial resemblance to a perforated gastric ulcer was marked, and its most important clinical feature. This diagnosis was ruled out finally on physical signs, especially gastric distension. It was argued that in all cases of stomachic ulcer the distension of the stomach is a most potent index of the necessity for immediate operation. No microscopical report of the thrombus was at hand.

Bland-Sutton reported the removal of a large and wandering spleen from a woman already the mother of seven children, and at the time of the operation two months pregnant. No difficulties were encountered from any source. Eighteen months after the operation she showed no symptoms of abscess of the organ. This case constitutes the seventh healthy and living patient in whom splenectomy had caused no inconveniences. In reply to queries he stated that he now never operates in cases of leucocythemia, having had one death in a twenty-six-year-old woman, whose white corpuscles were twenty to one

thousand red cells. For forty-eight hours she had done well, when with great abdominal distension, without signs of internal hemorrhage, she died. Furthermore, now, if the white cells are double their normal amount he refuses to interfere. Spleniculi he had never found, although he has examined for one in each case.

C. WILLIAMS had recently a patient, male, forty-three years old, primary syphilitic sore in December, 1896, secondaries in full development January 10, 1897. Mercury was exhibited chiefly with alternations of potassium iodide for eighteen months, when he ceased treatment, apparently cured. January, 1900, influenza attacked him, and April 14 what seemed to be post-influenzal intermittent fever appeared, four days later periosities were found on the right clavicle, and afternoon rise and morning fall of temperature were present. Syphilitic pyrexia was diagnosed. Under appropriate treatment the fever disappeared in seven days. At the present time the patient is well and fat. Literature shows that John Hunter recognized syphilitic fever, and many other cases are reported.

SOCIETY PROCEEDINGS.

CHICAGO PATHOLOGICAL SOCIETY.

Stated Meeting, Held November 12, 1900.

The President, Dr. Ludvig Hektoen, in the Chair.

Dr. D. N. Eisendrath demonstrated specimens as follows:

Adenoma of the Liver.—It was an accidental finding in an autopsy of a girl, twenty-one months old, who had been under the care of Dr. I. A. Abt in the Michael Reese Hospital from September 25, 1900, to October 12, the date of her death. Her clinical history was that of a typhoid fever with multiple gangrene. At the autopsy an area about the size of a hen's egg was found occupying the entire upper portion of the left lobe of the liver, causing a retraction or umbilication of the capsule over it. The sections made through this mass revealed a tumor sharply demarcated from the surrounding liver tissue, having a wavy outline with a slightly yellowish outer and a whitish, more fibrous inner portion. It was of firm consistency, and was at first regarded as a carcinoma. Microscopically the structure was seen to be that of an adenoma. The most striking features are the large size of the cells and the drops of fat which they contain. Whether to call this tumor an adenoma or simply a nodular hyperplasia is still an open question. Ziegler believes that they are true adenomata, although he thinks that there is no sharp line to be drawn between these and a nodular hyperplasia on the one hand and an adenosarcoma on the other. Orth states that there may be a true hyperplasia of the liver parenchyma, as where a large portion of a lobe has been destroyed by an abscess, syphilis or echinococcus. He has observed a distinct hyperplasia resembling an adenoma in granular atrophy and in a case of thrombosis of the hepatic vein. The same occurs in cirrhosis. The condition may be quite nodular and may be single or multiple, varying from a pea to a cherry in size. He believes that if such a condition is named an adenoma it would be better to call it hyperplastic to distinguish it from the tubular variety. In this latter form there are columns of cells, many having a distinct lumen. Both of these varieties may easily change into a carcinoma.

Diseases of Gall-Bladder and Infective Cholangitis.—The second specimens were from the same baby. The father was in the hospital with typhoid fever at the time of the baby's admission. The clinical course, previous history and frequently repeated Widal tests confirmed the diagnosis of typhoid fever. Death occurred Oct. 12, 1900. The portion of the autopsy to which special reference will be made is that of the liver and intestines. The latter showed a very marked swelling of the solitary follicles of the ileum and especially an appearance of Peyer's patches like that of the first week of typhoid in adults before ulceration has begun. The spleen was very much larger than normal, soft and pulpy. The liver was larger than in a child of this age; of a light brownish color and somewhat soft. Over the entire surface, irregularly scattered, was a large number of whitish areas with a red periphery about the size of the head of a pin. On section these were seen to be scattered uniformly through both lobes. In the left lobe was in addition the adenoma just described. Microscopically these areas are seen to be due to a necrosis of the parenchyma adjacent to the interlobular vessels. The liver cells in these are swollen, do not take the stain, and show all signs of cell death. Around each bile-duct near these necrotic areas there is a marked round-celled infiltration. There is a typical inflammation of the bile-passages (angiocholitis) or biliary hepatitis, as Ziegler calls it, with the resulting necrosis of liver cells. Cultures were made from the gall-bladder, liver and skin, but only in the latter were micro-organisms found (staphylococci). The necrosis is most typically shown in specimens stained with methylene blue or Bismarck brown. Such necrosis may be due either to stagnation of bile alone or this combined with infection. If to the latter, the micro-organisms most frequent as causal agents both clinically and in experimental investigations are the typhoid bacillus, the colon bacillus, the ordinary pus cocci, and the distoma hepaticum. Angiocholitis and such areas of necrosis have been produced experimentally by Netter, Homen, Roger and others with the colon bacillus. In this case of Dr. Abt the infection must unquestionably have been due to the typhoid bacillus which has been found in the gall-bladder and bile-ducts by Chiari and others. The subject of cholangitis and its relation to operations for gall-stones as a fatal complication is of the greatest interest.

Cardiac Anomalies.—Dr. Hektoen showed two rare cardiac anomalies: (1) Congenital aorticopulmonary communication, and (2) communication between aorta and left ventricle under the anterior aortic valve which was attached at both ends. Both occurred in new-born infants in the service of Dr. Cotton in the Presbyterian Hospital of Chicago. The case of aorticopulmonary communication is probably the tenth recorded and the first in America. A review of the clinical course of these cases was given. The second case is the first of its kind observed. It was urged that both the anomalies resulted from developmental disturbances in the septum of the arterial bulb.

Sarcoma of Pancreas.—Dr. Maxmilian Herzog read this paper for Dr. Geo. A. Boye, of Baldwin, Kansas. The paper gave a critical review of the literature of the subject. The case which is added to the list of previously recorded instances of sarcoma of the pancreas occurred in the practice of Dr. M. L. Harris, and was posted by Dr. Herzog. The patient was a man forty-seven years old, with no particular family or personal history. The tumor first gave rise to marked symptoms about a year before death. The urine never contained any sugar, not even after a glucose test-meal. An exploratory laparotomy revealed an inoperable tumor of the pancreas. At the autopsy there was found a tumor irregularly quadrilateral having diameters of 17, 20 and 24 centimeters. This large new growth filled the whole abdomen and had formed adhesions to neighboring organs; it had, however, nowhere broken into neighboring organs, nor had it given rise to metastasis. The microscopic examination of the neoplasm shows it to consist of large spindle cells taking their origin from the adventitious coat of vessels. Large tracts of the tumor show marked retrograde, degenerative changes, and there are cystic cavities in the new growths. No normal pancreatic tissue could be found. The kidneys showed parenchymatous changes; the spleen chronic splenitis, and the liver slight cirrhotic changes.

Dr. Hektoen, in the discussion, referred to a case reported by him in Volume II. of the *Society's Transactions*, and to a second case of small round-celled sarcoma of the pancreas, weighing 3000 grams, observed by him.

Dr. M. L. Harris said that in the case reported in the paper, sugar was not present in the urine, nor were there any other signs of a disturbance of the pancreatic function.

Dr. J. B. Herrick suggested the possibility of the tumor cells having an action similar to normal pancreas cells.

Dr. Herzog, in closing the discussion, in answer to a question of Dr. Herrick, said that the question with reference to the absence of glycosuria and the pancreatic ferments is a very interesting one. He entertains a definite theory concerning the pancreatic ferments, believing that the pancreas furnishes a ferment which splits the sugar and forms from it alcohol and CO_2. The alcohol again in *statu nascendi* is changed by processes of oxidation into H_2O and CO_2. He is not in a position to prove this hypothesis. On examining the tumor pieces were taken from various places. Nowhere could any normal pancreatic tissue be found. These negative findings do not prove much, since there might be hid normal pancreatic tissues somewhere in this very large tumor.

Carcinoma of Sebacceous Glands of a Rat.—Dr. Leo Loeb demonstrated this specimen. The tumor had grown in a few months to the size of almost half the head of the rat. It was ulcerating. It grew again to its original size inside of a few weeks after partial removal. Microscopically one sees enormously large sebaceous glands, branching out into different directions. At some places the skin covers the glands. The newly-formed tissue takes after some time the appearance of sebaceous glands. At other places one sees deep in the connective tissue more or less changed, isolated sebaceous glands. They may form alveoli of spindle-shaped cells. Near the normal skin the ordinary sebaceous glands show epithelial processes, that is, perhaps beginning carcinomatous change. That was not a secondary union, because there were no other carcinomatous alveoli near them, but it may be a regenerative growth. That demonstrates (*a*) direct outgrowth of glands as the first change in carcinoma; (*b*) anaplasia of tumor cells is not a primary factor underlying carcinomatous change.

Lymphosarcomatosis in a Sheep.—This specimen, exhibited by Dr. Loeb, is probably the first case of lymphosarcomatosis reported in an animal. There were many non-hemorrhagic nodules of different size beneath the skin and the fascia. There were tumors in the thyroid gland, in the kidney and in the heart muscle. The reticular network was best seen in the skin tumors. At the margin of the advancing lymph-cells, between the tubules of the kidney, no reticulum was present. At other places small spindle-shaped cells were found among the lymph-cells. The latter showed many mitoses. In the thyroid many cysts, partially lined with epithelium, were separated by lymphoid tissue At some places the lymph-cells broke through the epithelial layer.

Cytological Studies.—Mitoses and cell-divisions in different stages in eggs of guinea-pigs' ovaries were shown by Dr. Loeb. Such observations have been made by Hemeguy and Janosik. A large number of cells may be derived from one egg. One single cell situated in a mass of cells which originated by cleavage of one egg may show three or perhaps more nuclei. Nuclear division may therefore precede cell-division in rapidity. Atresic changes in the follicle take place at the same time Large cells are made up; each one may be made up of as many as twenty of the degenerating small, follicular, epithelial cells. It could not yet with certainty be made out if these phagocytic cells are the deepest follicular cells or the connective-tissue cells of the theca interna. The latter can probably change in this way.

NEW YORK ACADEMY OF MEDICINE—SECTION ON MEDICINE.

Stated Meeting, Held November 20, 1900.

John H. Huddleston, M.D., Chairman.

Early Recognition of Typhoid.—Dr. J. K. Crook said that the important diagnostic point for the general practitioner is the early recognition of disease and especially of such diseases as typhoid fever. No amount of care will absolutely guarantee against delay in recognition, because typhoid fever often begins with symptoms simulating some other disease. As in the case of the Czar of Russia, it may begin with influenza symptoms. In a recent case in the practice of Dr. Crook the beginning of the typhoid fever took on all the appearances of an ordinary lumbago. The early symptoms of typhoid may be considered to be those which occur from the inception of the disease until the fever reaches its fastigium, usually seven or eight days later. Not until the third day do any distinctive symptoms occur. The patient usually complains then of having felt below par for several days, of having had a headache, some shiveriness, some nausea which occasionally goes as far as vomiting, while indefinite pains occur in all parts of the body. Of these pains the most important is the headache which is an almost constant symptom and should arouse suspicion. Often at this period there will be a dry, disagreeable cough and frequent yawning spells. Often, too, the patient will complain of some looseness of the bowels. If perchance he has taken a cathartic, as will not infrequently be the case, this has acted with much more vigor than usual. His tongue will be dry, furry, somewhat coated, and his breath will usually be altered in odor.

Temperature.—Usually at this period, if the patient comes in the morning, no temperature will be noted. If he comes in the afternoon, one to two degrees of fever may be noted. Most important information can be obtained from the frequent use of a thermometer at this time. The patient should be instructed to take his temperature several times a day, and note for the information of the physician its height and the hour. Even at the third day variation in temperature sufficient to excite suspicion will always be found. Pressure upon the right iliac region at this time will often cause gurgling. This symptom is, however, not of much importance as it occurs always during diarrhea and will often be found in perfectly healthy individuals.

Fifth Day.—Usually at this time the patient will not feel well enough to leave his house. When asked to show his tongue it will be distinctly tremulous and there will be a tremor of the fingers when they are extended, or when they are employed to button garments, or to pick up small objects. At this time, too, distinct fever will always be found, usually as high as 101° sometimes running to 102° F. Meteorism will be found and tenderness can be elicited in the right iliac fossa, although there is no spontaneous pain. Upon careful percussion, the spleen will be found to be enlarged; the diarrhea will often be marked and in general little doubt of the character of the disease remains. If the affection occurs during the autumn it is now time to inaugurate a strict dietetic regime, such as is used in typhoid fever.

Seventh Day.—At this time there will be marked prostration. The patient will be glad to stay in bed, there will be less headache, perhaps, but the patient will be more apathetic, careless about business matters, and other interests and the signs of a serious illness will be easily recognizable. The pulse is soft and sometimes dicrotic. While the temperature will usually have taken the characteristic step-like rise of typhoid fever, anomalous febrile courses are not unusual. Any case may run a temperature quite apart from the regular typhoid fever course. At this time the spleen will be found to have still further increased in size and the absolutely pathognomic sign of the disease, the characteristic eruption, will be found in most cases if carefully looked for. This consists of rose spots, slightly elevated, which disappear on pressure. They may occur anywhere on the body, though their usual situation is the vicinity of the umbilicus. The spots should be looked for on the back and buttocks; occasionally they will be found on the limbs. Two or three are as significant as two or three dozen. At this time an examination of the urine will show the presence of Ehrlich's diazo-reaction. Dr. Crook has never missed it at about the seventh day. This reaction, though considered pathognomic at one time, is not so, but occurs in measles and also in pthisis florida.

Widal Reaction.—This is, of course, our best method of diagnosticating typhoid fever. Unfortunately, it does not occur at times until rather late in the disease. It occurs in practically all cases, however, and when it does occur it is positively significant.

Possibilities of Early Diagnosis.—We may say, then, that typhoid fever should at least be suspected on the third day. It can be diagnosed with reasonable assurance on the fifth day, provided all the possible sources of information are thoroughly investigated. There should, as a rule, be no room left for doubt on the seventh day if all the means which modern diagnosis have put at our command are made to furnish their full quota of information.

Home Bathing in Typhoid.—Dr. Simon Baruch described certain hydropathic methods by means of which patients suffering from typhoid can be treated for pyrexia without the necessity for a bathtub. He insisted that cold water, besides mechanically reducing the temperature by actual abstraction of heat, stimulates the circulation. This second purpose, however, of cold applications is only accomplished if friction accompanies the use of cold. The presence of the toxins of typhoid fever in the circulation relaxes

the arterioles all over the circulation and so makes harder work for the heart. The application of cold then helps the circulation by toning the arterioles, thus making the blood paths narrower and the heart's pumping easier. Clinically this result can be observed by the disappearance of cyanotic conditions after the bath. Typhoid patients always look better after the bath; when they do not it is because some element in the technic has been neglected. The effect of the bath on the kidneys is like a summer shower on the parched plants at the end of a heated spell. Toxic materials have gathered as sources of irritation, just as dust gathers on the leaves of the plants, and when the circulation is toned up the narrowing of the lumen of the capillaries in the kidney sends the blood more rapidly through them, flushing them out and making diuresis more complete and efficient.

Reaction After the Bathing.—Reaction must follow cold bathing always, or the purpose of the bath is rendered abortive. We might think that emphasis need not be placed on this point in our day. Consultation of some of the text-books, however, shows what mistaken notions may be conveyed by ill-given directions. Lauder Brunton, the distinguished English therapeutist, in his text-book of therapeutics, edition of 1898, says that when the patient's temperature reaches a certain point he should be placed in the bath and left there until his temperature comes down. When he is first put in the temperature of the water should be about 65° F. and this may be reduced by additions of colder water or ice to 40° F. It is no wonder that he concludes his directions with the advice to remove the patient from the bath before his temperature becomes quite normal, because it may sink still lower after the patient is put to bed and symptoms of collapse may ensue. The main purpose of the bathing is neglected if these directions are followed and no friction is employed during the bath. No wonder under such circumstances that the bath should prove an unpopular remedy.

Cold Coil.—The use of rubber tubing through which cold water is allowed to flow is usually a mistake. It does produce local lowering of the temperature, but absolutely without any compensatory stimulation. After its application the skin will be found blue and pallid. For nearly the same reason sponge baths, as they are usually given, are objectionable. The application of cold water in this way does lower the temperature, but it fails to produce any other good effect. Remedies for fever, it should be borne in mind, must be antifebrile as well as antipyretic. Antifebrile therapeusis modifies all of the symptoms produced by the fever, especially the relaxation and tendency to exhaustion. Antipyretics only reduce the temperature, but without affecting other symptoms of the fever. Above all, remedies must encourage the elimination of toxins from the circulation. This is best accomplished by general stimulation that makes every organ do its work better and so arouses the reactive vitality.

Cold Rubbing.—Patients whose temperatures are above 102.5° F. should be rubbed with a wash-cloth wrung out in cold water. As soon as the patient shows any signs of chilliness that are not relieved by the friction, the rubbing should cease. When his temperature reaches the same point as before, water five degrees colder in temperature should be employed and more friction exercised. After this a compress wrung out in cool water may be placed over the abdomen. This should be carefully covered with flannel and its application overseen with the greatest care and, as a rule, not left to an inexperienced person. If the patient's temperature reaches 103° F., or if nervous symptoms occur, a towel-bath may be given, the patient being covered with a towel over which cupfuls of cool water are poured, each cupful being well rubbed in, the important thing is to act quickly and stop when the teeth begin to chatter.

Ice-Rubbing.—When the patient's temperature remains persistently high and bathing facilities are not at hand, the patient may be rubbed with a smooth piece of ice. Each rubbing with ice is followed by a hand-rubbing until the part glows. Thus successive parts of the body are cooled and rubbed up.

Cool Water Drinking.—It is important that plenty of cool water should be given to the patient during the course of the fever. Four to six ounces of water at a temperature of forty degrees may be given whenever desired and, if water is not craved, a regular system of giving draughts of water at certain times should be established. If the system of rubbing and internal administration of cool water be faithfully and regularly kept up, tubs are often unnecessary even in severe cases. Under this method of treatment it is especially noteworthy that the amount of urine increases very satisfactorily and nephritic symptoms disappear. This system of rubbing is especially of benefit when baths are contra-indicated, as in pneumonia or tendencies to hemorrhage.

Giaourdi, a New Milk Food.—Dr. Achilles Rose described and presented samples of this sterilized, fermented milk preparation which is used very extensively in Greece as a popular article of diet and has been found to be of value in the treatment of typhoid fever and gastric ulcer. The ferment used in the preparation of the new food is obtained from dried figs. The food itself is a very pleasant, acid, gelatinous substance not unlike thick milk, but of more consistency and less acidity. Dr. Rose has found it an excellent addition to the diet for certain patients with whom milk did not agree and to whom matzoon and kumyss were distasteful. Giaourdi is not a proprietary article. It can be rather easily prepared. Practically all the Greeks in the city know how to make it by tradi-

tion, and it promises to form a useful adjunct in dietetic therapeutics.

In the discussion Dr. E. Quintard said that he had found giaourdi very useful in certain stomachic affections, notably stenosis of the pylorus with very little stomachic digestion, the so-called ischochymia. In patients in whom curdled milk would not pass the pylorus, this new food preparation proved an important article of diet. In neurasthenia with stomachic symptoms and the capricious appetite which often accompanies this condition, giaourdi also proves useful. In a recent case of myasthenia gastrica, in which kumyss proved only a disturber of digestion, the new food preparation was well borne.

Dr. Loewenstein said that she had examined specimens of giaourdi in order to determine the character of the fermentation it had undergone. No alcohol could be found in the sample submitted and the changes induced in the milk were evidently due to some other than the alcoholic fermentation. A certain amount of rennet is used in the preparation of the new food and it is thought that possibly this is the only active agent present. The addition of dried figs, however, to milk causes a delicate curdling which shows that there is a labferment contained in figs. Dr. Loewenstein was reminded of the fact that while traveling several years ago in Switzerland she talked with an Alpine peasant who was said to have a secret for the manufacture of cheese. His cheese was famous throughout all the country. He confided to her that he used in addition to rennet a watery solution of figs for the coagulation of the milk. This made his cheese taste better and gave it a special market value. The curdling produced by the fig ferment is very delicate. Doubtless this addition of figs to the milk counteracts a certain tendency to constipation which most milk foods occasion.

Milk-Food Preparations.—Dr. Einhorn said that any new milk food is a welcome addition to dietetic therapeutics. Milk as practically an exclusive article of diet must be used so frequently that any possible variety in its taste is a valuable aid if the nutritive value of the milk is not interfered with. Thick (sour) milk constitutes a valuable article of food of which sufficient use is not made by the modern physician. Dr. Einhorn has tasted, in Russia particularly, samples of thick milk that resembled very much this food presented by Dr. Rose. The thick milk, especially when served with cream and a little sugar, forms a very pleasant and, needless to say, an extremely valuable article of food. This requires no special preparation and keeps well unsterilized for a week to ten days. In Russia cheese is made by allowing jars to stand for a week and then removing the cream and using the curdled milk beneath for the cheese. Dr. Loewenstein said that the preparation presented by Dr. Rose is very different from mere curdled milk, because even boiled milk curdles on the addition of the labferment from the figs.

In closing the discussion, Dr. Rose said that clinically this preparation differs very much from sour milk, because it will be found to agree with many patients to whom the slightest amount of lactic acid causes digestive disturbance. Moreover boiling the milk before giaourdi is prepared sterilizes it, at least as far as pathogenic germs are concerned, and adds another element to the desirability of this new food as an addition to the dietary of invalids whose resistive vitality is often notably lowered.

Typhoid Treatment in the New York Hospital.—Dr. Frederick L. Keays read a paper with this title (see Medical News, p. 937).

Gastric Ulcer and Mucomembranous Colitis at the Paris Congress.—Dr. James J. Walsh then read a paper on this subject. It will appear in a subsequent issue of the Medical News.

Gastric Ulcer and Gastric Juice.—In the discussion Dr. Einhorn said that gastric ulcer is not due alone to the presence of gastric juice. Ulcers of the stomach have sometimes been demonstrated clinically and at autopsy in patients in whom there was an entire absence of gastric secretion. In one case an ulcer was found where there had been no gastric secretion for over two years. The fact that the typical conical ulcer occurs only in the stomach itself, in the duodenum and in the lower part of the esophagus, points to the fact that the gastric juice is an important element in the etiology of gastric ulcer, but it is not the only one.

Operations for Gastric Ulcer.—With regard to surgical intervention for gastric ulcer, Dr. Einhorn is of the opinion that this branch of surgery may easily be overdone. He hesitates as yet to counsel an operation unless the case is an extreme one. Profuse hemorrhage alone can scarcely justify resort to surgical measures. Over 75 per cent. of patients who suffer from profuse hemorrhage get entirely well on ordinary medical treatment. The mortality of operations upon the stomach is over 20 per cent. so that practically nothing is gained in additional safety for the patient by recourse to surgery. The decision in such cases is a most difficult one. The appeal to the occurrence of contractions of the stomach after the cure of ulcer as a reason for early operation seems far-fetched. Dr. Einhorn does not think that operations should be done for pyloric stenosis until the gastric equilibrium is seriously disturbed by gastric retention.

The Mucomembranous Colitis.—Dr. Einhorn considers that this affection is essentially nervous in character. It has been said that the very name adopted for it, colitis or inflammation of the colon, shows that authorities are agreed that there is a pathological inflammatory condition as its basis. The name was adopted, however, before the true nature of the disease was suspected and has been retained in order not to in-

troduce confusion by changes of terminology before some general agreement as to the proper name for the affection could be entered upon.

Hyperacidity and Gastric Ulcer.—Dr. F. F. Ward said that he has never been quite able to make up his mind as to whether the gastric hyperacidity which occurs so commonly with gastric ulcer is a cause or effect of that lesion. The presence of the ulcer certainly causes an irritative condition of the secretory glands of the gastric mucous membrane. This leads to hyperacidity. Whether this hyperacidity exists before the development of the ulcer causes it and then renders it chronic by a sort of vicious circle, remains to be investigated.

An Anomalous Case.—Dr. Ward gave the details of a recent case under his care in which the symptoms of gastric ulcer proved obstinate to all treatment. An operation was performed and to the surprise of all concerned a distinct tumor was found in the pyloric region. The patient was in no condition for an extensive resection of his stomach so that a gastro-enterostomy was done in the hope that his nutrition would improve as a consequence. After this operation he rapidly gained in weight. At the end of six weeks he was in such good general condition that another operation with the idea of removing the tumor was undertaken. No tumor was found. Afterward the man continued to gain in weight and strength and had absolutely no recurrence of his gastric symptoms for over six months. Then the symptoms of his original ailment recurred. Hyperacidity was noted and afterward achylia gastrica developed. Lavage was practised and gave considerable relief from the symptoms. He came one evening suffering from severe distress in the epigastric region. Lavage would have been practised but for lack of time. The pains continued and became so severe during the night that a surgeon was called in. He performed an operation and found a perforation of the stomach. The patient died from septic peritonitis and the stomach was found adherent to the abdominal walls while in the scar a large malignant growth had developed. It was through the cancerous tissue that the ulcerative perforation had taken place.

Minute Gastric Ulcers.—Dr. E. Quintard called attention to the fact that Dieulafoy had described certain cases in which there occurred tremendous hemorrhage from the stomach that proved obstinate to all treatment. At autopsy no lesion of the mucous membrane of the stomach could be found to account for the hemorrhage. When the gastric mucous membrane was carefully gone over with a magnifying glass a tiny erosion was found which had eaten its way into the side of one of the smaller gastric arteries. As the artery had not been completely cut through the normal mechanism for the prevention of hemorrhage by contraction of the arterial coat failed of accomplishing and the hemorrhage continued. The only way by which the hemorrhage could be stopped was by clotting at the point of erosion. Owing to the movements of the stomach, especially the vomiting, this is difficult and so the hemorrhage continued. In one of these cases absolutely no arterial sclerosis was found and there was no sclerosis of the liver; the patient suffered from a certain amount of alcoholic gastritis. It is probable that some of the so-called nervous hemorrhages from the stomach, that is, hemorrhages without any pathological lesion of the gastric mucous membrane, are really cases of this form of very minute erosion into a blood-vessel, the erosion escaping notice in the ordinary macroscopic examination of the mucous surface.

SPLENIC ANEMIA—ANEMIA WITH ENLARGEMENT OF THE SPLEEN.*

By ALOYSIUS O. J. KELLY, A.M., M.D.,
OF PHILADELPHIA;
INSTRUCTOR IN CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA; ASSISTANT PHYSICIAN TO THE UNIVERSITY HOSPITAL; VISITING PHYSICIAN TO ST. AGNES' HOSPITAL, ETC.

THE occurrence of a symptom-complex characterized especially by grave and progressive anemia and enlargement of the spleen, but unassociated with leucocytosis or enlargement of the lymphatic glands, has been recognized for a long time. The first undoubted case of this nature was probably described by Woillez,[1] in 1856. A case of a similar affection in a child, aged ten months, was reported in 1866 by Gretzel[2] from Griesinger's clinic. The attention of the profession in this country was first directed to the subject in 1871 by H. C. Wood,[3] who described the disorder as the splenic form of pseudoleucemia. To Banti,[4] in particular, however, is due the credit of having directed renewed attention to the occurrence of the disease in 1883; and to the recent publication of more exhaustive articles by Bruhl,[5] West,[6] Sippy,[7] and Osler[8] is attributable the fact that the profession is now tolerably familiar with the chief clinical characteristics of the disorder.

This symptom-complex of progressive anemia with enlargement of the spleen has been described under a variety of names, such as splenic cachexia, splenic anemia (Griesinger and Banti), primitive splenomegaly (Debove[9] and Bruhl), idiopathic hypertrophy of the spleen without leucocythemia (Gaucher[10]), and the like. The designation splenic anemia has been employed by most of the recent writers on the subject, such as West, Taylor,[11] Coles,[12] Osler, Morse,[13] Jackson,[14] Stengel,[15] and others. The majority of these authors, however, have adopted splenic anemia as a convenient temporary designation to indicate the principal clinical features of a morbid condition the nature of which is not understood, and concerning the independent existence of which, as a clinical entity, considerable doubt has been expressed. On the other hand, Sippy who, recently reporting a personal observation, contributed also a most thorough review of the literature of the subject prefers the designation splenic pseudoleucemia, as does also Cabot.[16] Inasmuch, then, as the nature of the disease is little understood, and as the number of reported cases is small, it may not be unprofitable to add another. My case is as follows:

M. E. K., single, white, female, aged twenty-two years, and a native of the United States, was first seen by me in private practice, February 2, 1900. The following history was elicited: Her father died in middle-life after an operation for the cure of an ischiorectal abscess. He was in good health until one year prior to his death, when he suffered from a disorder of the ischiorectal region. Under medicinal treatment he recovered and resumed work. In a short time he was again attacked, was compelled to submit to operation, and died soon afterward. The patient's mother is living and well. Of seven brothers and sisters, one brother died following an operation for the cure of appendicitis, and five others died of causes not ascertainable. One brother is living and well. Aside from the fatal affection of the father, there was no history of tuberculosis, carcinoma, or other serious complaint in the family.

The patient herself during childhood had measles, chicken-pox, pertussis and pneumonia, the last named at the age of seven years. After this illness she remained in good health until she was seventeen years of age, when she contracted acute inflammatory rheumatism. The joint lesions were migratory and most of the larger joints were more or less involved. After about six weeks she made a good recovery, but subsequently she had several minor attacks. Menstruating first at the age of fifteen years, her periods were always regular and painless until January, 1900. The flow usually lasted three or four days and was generally rather profuse. She has always lived in Philadelphia and has never had malaria.

The patient, though never robust, remained in good health, working steadily as a clerk until May 13, 1899, when she was compelled to cease work. For about a week prior to this date she had been feeling badly—complaining of a cold. She was tired, somnolent and weak; the slightest exertion exhausted her and her appetite failed. Despite intermittent medical attention, she remained in about this condition throughout the summer of 1899, but during the fall she improved a little. Toward the end of the summer she sustained a fall. To the effects of this was attributed a rather severe pain in the left side in the region of the spleen that came on for the first time during September and continued for several weeks. A number of minor attacks of pain in the same region occurred at intervals subsequently and were the cause of great anxiety on the part of the patient and her mother. Toward Christmas, 1899, the patient's general health grew worse; palpitation of the heart and dyspnea supervened, both were much aggravated on exertion, and the patient was obliged to take to bed. A few days later there developed an attack

*Read before the Section on General Medicine of the College of Physicians of Philadelphia, October 8, 1900.

of what was said to have been rheumatism in the right hip. The pain and tenderness on motion of the joint continued for about five weeks. In January, 1900, there occurred suddenly a severe hemorrhage from the genitals, it being reported that at least a quart of blood was lost. The bleeding did not continue more than twenty-four hours, and the patient menstruated regularly at the end of a week. Aside from this there had been no hemorrhages whatever—no nose-bleed, no expectoration nor vomiting of blood, no passage of blood by the bowel and no suspicious alterations in the urine.

At the time of first observation the patient complained of extreme asthenia, palpitation of the heart, dyspnea, lack of appetite, some epigastric distress after eating, and marked constipation. The dyspnea was more or less constant and was much aggravated by any exertion, talking for instance. In addition, she had now and then slight headache and some vertigo. She had been continuously in bed since Christmas, and she was quite irritable, nervous, and impatient at her slow recovery (I being her third physician). The pain in the right hip was almost entirely gone.

Examination showed the patient to be a slight, fragile, poorly-developed girl, with slender, bony framework, and soft, flabby musculature. Though the patient had never been very robust nor rotund there was evident a moderate degree of emaciation. The skin and visible mucous membranes were quite pale, but the latter were not pigmented. However, the skin, particularly that of the backs of the hands, forearms, and chest revealed a number of mole-like spots of pigmentation. These varied somewhat in size, the average size being about that of a split pea; they were quite dark, circumscribed, not elevated, and contained no excess of hairs. The patient thought that she had had most of them as long as she could remember, but she was inclined to believe, possibly upon suggestion, that they had become more numerous since her first attack of rheumatism at the age of seventeen years. There was no diffuse pigmentation; neither was there any cyanosis, edema, enlargement of the superficial lymphatic glands or tenderness over the sternum or along any of the long bones. The neck was long and thin and revealed pulsation of the veins on both sides. These were more marked on the right side and were evidently false venous pulsations transmitted from the underlying arteries. The chest was comparatively long, of poor anteroposterior diameter, and narrow. Physical exploration of the lungs showed them to be normal. The apex beat of the heart was in the fifth interspace just within the nipple line. No thrill was palpable. The superficial cardiac dulness was irregularly triangular in outline. It extended upward to the top of the fourth rib where it joined the sternum; to the right, just a trifle to the right of the left edge of the sternum; and, to the left, to the position of the apex beat. The heart's action was regular and the sounds were normal. Toward the base of the heart, however, there was faintly audible a blowing systolic murmur. This seemed to have its point of maximum intensity toward the pulmonary region, but it could be heard also over the fourth rib midway between the sternum and the nipple. The pulmonary second sound of the heart was short and valvular, but considering the thinness of the chest wall, it did not seem unduly accentuated. The liver dulness extended in the nipple line from the top of the sixth rib to the free margin of the ribs; the organ itself was not palpable. The splenic dulness extended in the midaxillary line from the eighth interspace to two fingers' breadth below the free margin of the ribs and anteriorly about the same distance beyond the ribs. The organ was distinctly palpable. It was hard and regular in outline, and the notch could be distinctly made out. The region was slightly tender to palpation. Examination of the abdomen was otherwise negative; in particular, there was no ascites. The patient's temperature was 103.5° F.; her pulse-rate 100—the pulse itself soft and compressible; and her respirations were 24 per minute. Inquiry at this time elicited the fact that she had had fever for six weeks (the time during which she had been in bed). I subsequently learned from the physician who had been in attendance prior to me that she had had fever, varying from 102° to 103° F. and over, and enlarged spleen for four weeks (the time during which he had been in attendance).

The patient's urine was examined February 4th, with the following result: Specific gravity 1017, acid in reaction, no albumin and no sugar; microscopically there were no casts but a considerable deposit of urates. Examination of the genitals failed to reveal any pathologic condition.

She was advised to remain in bed and was encouraged to drink largely of milk which she had previously absolutely refused. Constipation, which had been obstinate, was gradually overcome by cascara sagrada, salines, and enemas when necessary. Later, when the dietary was increased, fruits subserved the same purpose. She was given tincture of nux vomica, fifteen drops three times a day. Her blood was examined February 14th with the following result: Hemoglobin 50 per cent., erythrocytes 3,200,000, leucocytes 8200, color index of the erythrocytes 0.78. The erythrocytes were pale, but no abnormal forms were seen. Differential count of the leucocytes revealed the following: Small mononuclears 13 per cent., large mononuclears 7 per cent., transitionals 3 per cent., polynuclear neutrophiles 75 per cent., and eosinophiles 2 per cent. At the end of three weeks the constipation was finally overcome and did not recur. The bowels were moved once daily until about April 15th, when diarrhea set in. This was of moderate severity and entirely independent of any discoverable cause. It persisted for several days and then ceased. Later,

however, there occurred a number of other attacks of varying severity. Although it had been learned from the physician previously in attendance that five drops of Fowler's solution had been followed by manifestations of intolerance, it was determined on February 24th to try this again, and it was commenced in three-drop doses three times a day. At the same time Blaud's pills also were given—five grains three times a day. The nux vomica was continued. One week later the dose of Fowler's solution was increased one drop three times a day every four days, and a raw egg and a half ounce of Sherry wine were added to a glass of milk twice a day. Blaud's pills were increased to ten grains three times a day.

By April 1st her general condition had improved materially; but on this date she contracted an attack of acute articular rheumatism in the right wrist; there was also a little pain and tenderness in the left ankle, but no swelling. The attack subsided under salicylates in about eight days. From the first time that I saw the patient until the day of the onset of the attack of rheumatism, her fever had always been 102° to 103° or 103.5° F., in the evening. On two occasions it was 104° F. It was not increased during the attack of rheumatism. After the subsidence of the latter Fowler's solution and Blaud's pills, which had been temporarily withheld, were resumed. During the last week in April she suddenly at night suffered a most acute pain in the region of the spleen, accompanied by marked prostration, almost collapse. The region of the spleen was excessively tender and the spleen itself seemed to have increased a little in size—it extended beyond the free margin of the ribs almost if not quite three fingers' breadth. Over the spleen a friction fremitus was slightly palpable and distinctly audible. It was much augmented, as was also the pain, by rapid and deep respirations. At the end of four days she had recovered her former fair general condition, but the tenderness in the region of the spleen persisted for a couple of weeks. Later there occurred a number of similar attacks of pain in this region, but none of the severity of the one just mentioned. They were interpreted as attacks of perisplenitis. By May 15th she was taking 10 drops of Fowler's solution three times a day without manifestations of intolerance, and she had so far improved as to be able to get out of bed. This she was encouraged to do, as well as to drink liberally of milk and to partake of a more extended diet, including meat. This she rather objected to, but with encouragement she managed to take a little meat at least once in four or five days of every week. Sweatings, which on a number of occasions during the latter part of March and the whole of April had been profuse, ceased almost entirely. At this time (May 15th) examination of her blood revealed the following: Hemoglobin 60 per cent., erythrocytes 3,800,000, leucocytes 6700. color-index of the erythrocytes 0.78. The red corpuscles were pale, but no abnormal forms were detected. The differential count of the leucocytes was as follows: Small mononuclears 19 per cent., large mononuclears 6 per cent., transitionals 4 per cent., polynuclear neutrophiles 70 per cent., and eosinophiles 1 per cent. During the third week in May the patient surprised us by going downstairs by herself unannounced. Fever had continued and ranged between 100° and 103° F.; on several occasions it reached 104° F. On one or two occasions it was but 99° F. in the late afternoon. While she was not advised to go downstairs, she was permitted to do so on several occasions, and twice she rode in the park in a carriage. She was rather encouraged to go from her bed-room to an adjoining room and to sit in the sunshine as much as possible. Her condition at this time, while not reassuring, was satisfactory. So much so that the question of operative intervention for the removal of the spleen, a subject which had been broached before, was again presented to the patient and her mother. Its possibilities and dangers were adequately explained. In view, however, of the unfortunate outcome of operative work on the persons of the father and son, removal of the spleen, which was not urged by me, was positively declined. Toward the end of May the general condition of the patient began to grow worse, and by the first week in June it became apparent that the fatal termination was but a question of a short time. Her weakness grew manifestly worse, as did also her breathlessness and palpitation of the heart. Indeed, the dyspnea was such an obtrusive symptom of the disease that, together with the increasing anemia and enlargement of the spleen, it may be said to have dominated the clinical picture. Her appetite became capricious and varied considerably. Attacks of diarrhea, which of late had become more frequent, now became also more severe and protracted. Examination of the blood revealed the following: Hemoglobin 33 per cent., erythrocytes 3,070,000, leucocytes 6300, color-index of erythrocytes 0.54. The erythrocytes were quite pale, many of them exceedingly so; there was considerable variation in their size, and a few of them were more or less distorted. In an examination of seven coverslip preparations two erythroblasts (normoblasts) were seen; one of them had a double nucleus. The differential count of the leucocytes was as follows: Small mononuclears 7 per cent., large mononuclears 5 per cent., transitionals 2 per cent., polynuclear neutrophiles 85 per cent., and eosinophiles 1 per cent. With continued fever, increasing pallor and exhaustion, dyspnea and palpitation of the heart, both of which latter became much aggravated in paroxysms at night, the patient finally died June 19, 1900. With the single exception that the systolic murmur over the body of the heart had become louder, the physical signs had not varied appreciably from those already noted. The urine had remained as already stated. The blood condition had evidently become worse,

but another examination was not made. A necropsy was not permitted.

The establishment of the diagnosis in the case presented certain features of interest. It is reported that the physician first in attendance was inclined to the diagnosis of typhoid fever. There can be little question that in the early days of the patient's illness in bed this was not altogether an unpardonable mistake. The physician second in attendance, as the case progressed, became more and more inclined to the diagnosis of splenic anemia, and by the time I was in attendance the supposition of typhoid fever could be no longer entertained. It is interesting in passing to note that during January the patient's blood yielded a positive Gruber-Widal reaction by the dried-blood method and a dilution approximating 1 to 10. With higher dilutions, however, the response was negative. On two subsequent occasions the reaction was negative with dilutions approximating 1 to 10 as well as with higher dilutions.

It was a matter of comparative ease to exclude certain diseases associated with enlargement of the spleen, such, for instance, as echinococcus disease, tumor formation, amyloid disease, malaria, and cirrhosis of the liver. The enlargement of the spleen being uniform and firm was not of the variety we usually associate with echinococcus disease and tumor formation, and the course of the affection, as well as the general symptoms, readily served to exclude both of these affections. There was no cause for amyloid disease, neither were there any of the clinical manifestations of amyloid disease of any of the other organs. There was no history of past malaria, nor any evidence of present malaria. There was no ascites or other evidence of cirrhosis of the liver. Nor was there warrant for the supposition of the existence of Banti's disease—enlarged spleen, anemia, and cirrhosis of the liver. In regard to this affection described under his name, Banti admits the possibility of it being a late stage of splenic anemia, but he states that there is proof neither for or against such a supposition. He thinks that the two diseases may be distinct from the fact that in the late stage of splenic anemia, even if long continued, there occurs no macroscopic evidence of cirrhosis of the liver, whereas in his affection, splenomegaly with liver cirrhosis, the alterations in the liver are always present even if the disorder be of short duration.

From the first the disease impressed me as being either splenic anemia, splenomedullary leucemia, or some form of sepsis, more particularly ulcerative endocarditis. It seemed necessary, however, to exclude also passive congestive enlargement of the spleen and pernicious anemia. It was all the more important to exclude enlargement of the spleen, the result of passive congestion, because the patient had had several attacks of acute articular rheumatism, and because she presented a systolic murmur and the physical signs of enlargement of the heart. Aside from the dyspnea and palpitation of the heart on exertion the patient exhibited no signs of failing cardiac compensation. There was anemia rather than cyanosis of the skin and visible mucous membranes, there was no edema, and there were no evidences of congestion of the liver, kidneys, or lungs. The murmur was hardly of the character of that usually heard in mitral incompetency nor was its point of maximum intensity at or near the apex. It was borne in mind, however, that the murmur of mitral incompetency is sometimes heard best toward the pulmonary region. As further tending to disprove the existence of a lesion of the mitral valve, there was no marked accentuation of the pulmonary second sound. That a mitral insufficiency did not exist, I am not prepared to state; but I believe, on the contrary, that the murmur was correctly referred to the anemia, and the enlargement of the heart to a dilatation, also the consequence of the anemia. To this dilatation of the heart and the anemia were in turn attributed the dyspnea and palpitation of the heart. Whether or not a mitral incompetency also existed, the enlargement of the spleen was certainly not the consequence of passive congestion.

Pernicious anemia was excluded on account of the enlargement of the spleen and the condition of the blood. Enlargement of the spleen, though it does occur in pernicious anemia, is rarely if ever as great as that commonly found in splenic anemia. The difficiency of the individual red corpuscles in hemoglobin, the absence of marked variation in the size of the erythrocytes, the absence of microcytes and macrocytes, and the presence of but very few erythroblasts served also to exclude this condition. It may be remarked, however, that splenic anemia is a form of pernicious anemia, in that it is progressive and fatal. It may be also that future studies will indicate that in nature it is not wholly unlike the condition to which we now apply the designation progressive pernicious anemia. At present, though, there is little evidence to warrant such a supposition.

That the disorder in my patient was not leucemia was immediately evident at the first examination of the blood. The absence of leucocytosis seemed also to settle conclusively the question of sepsis or ulcerative endocarditis. Despite this, however, for a time I could not rid myself of the idea of the possible existence of ulcerative endocarditis. This was not unlikely due to the fact that during the previous winter I had had the opportunity to observe in the medical wards of the Hospital of the University of Pennsylvania, in the service of Dr. Musser, two cases of ulcerative endocarditis; I had lately performed a necropsy at the German Hospital on the subject dead of the same disease; and I had under my charge in private practice a girl of whose condition I had made a like diagnosis. The subject was therefore uppermost in mind. Several enumerations of the leucocytes alone, however, revealed the continued absence of

leucocytosis; the patient's general condition was hardly of the profound septic character that we associate with ulcerative endocarditis; there occurred no evidences of infarction of either the brain, spleen, kidneys, skin, mucous membranes, retina, or other portions of the body; there developed no roseola, erythema, urticaria, nor swellings of the joints, aside from the later attack of rheumatism in the wrist; there was no irregularity of the action of the heart; and, finally, the manifestations on the part of the heart were adequately explained as already narrated.

It seems to me, in the absence of the confirmative testimony of a necropsy, that the diagnosis of splenic anemia was justified from the absence of etiologic factor; the course of the affection, the enlargement of the spleen, the profound and progressive anemia of chlorotic type, the absence of leucocytosis, the absence of enlargement of the lymphatic glands, the pain and tenderness in the region of the spleen, associated on one occasion with palpable and audible frictions, and attributed to attacks of perisplenitis, the genital hemorrhage, the dyspnea, the diarrhea, the asthenia, the fever, and the moderate duration of the disorder.

There are several of the clinical features of the affection that merit a word in passing. In the first place it is of interest that the disease occurred in a girl. Of Osler's 15 cases, 12 occurred in males, and but 3 in females. Of West's 24 cases, 19 occurred in males, and but 5 in females. It is worth noting also that my patient was twenty-two years of age. With the exception of one, a girl aged eleven years, all of Osler's patients were over thirty-five years of age. Of 22 of West's patients, 13 were between the ages of twenty and fifty years. We may thus assume that the disease occurs with almost equal frequency throughout all periods of life. That a disease that bears at least a superficial clinical resemblance to splenic anemia occurs in children, even infants, cannot be doubted. Although the nature of the disorder as it occurs in children is as little understood as is its counterpart in adults, it seems not altogether unlikely that the two affections are dissimilar. It is well, however, not to confound the infantile pseudoleucemia of Von Jaksch with this condition; in the former there occurs a leucocytosis which is not present in splenic anemia.

The absence of enlargement of the lymphatic glands in my patient is but a clinical observation based upon an examination of the superficial lymphatics alone. Whether any of the deep lymphatics were enlarged, I am unprepared to state —lacking the testimony of a necropsy. It seems that in several of the cases that have gone to necropsy, slight or moderate enlargement of the retroperitoneal, mesenteric, and other glands has been found. It would appear from this that there is at least a little reason for the supposition advanced by some observers, that there exists a relationship between this affection and pseudoleucemia—a relationship warranting, in their opinion, the designation splenic pseudoleucemia. It is maintained by Osler, however, that "there is no warrant for the opinion that these cases of anemia splenica have anything to do with Hodgkins' disease (anemia lymphatica) from which the clinical picture is very different."

The enlargement of the spleen in my patient was not as great as that encountered by some observers. Whether it preceded or followed the development of the anemia, I am unable to state. Both were present when I saw the patient for the first time, and the patient even at that time was unaware of any abnormal growth in her abdomen. In the majority of reported cases the enlargement of the spleen seems to have been the primary event—hence the designation primitive splenomegaly employed almost exclusively by the French writers. I have no reason to doubt that in my case also the enlargement of the spleen preceded the anemia.

The hemorrhage in my case also was very interesting and of an unusual source—from the genitals. I have not read of a similar occurrence in any of the reported cases. The hemorrhages usually associated with splenic anemia are epistaxis, which may be repeated and profuse; gastro-intestinal hemorrhages, which were an interesting feature of a number of Osler's cases, hemoptysis, hematuria, retinal hemorrhages, or smaller hemorrhages into the skin and mucous membranes. It is well to remember the hemorrhagic tendencies of these cases, especially if any operation, such as removal of the spleen, be contemplated.

The dyspnea, particularly during the last month or six weeks of the life of my patient, was really extreme, especially upon the slightest exertion. As already narrated, with the enlargement of the spleen and the anemia, it seemed to dominate the clinical picture. Late in life the diarrhea also was an obtrusive symptom. The attacks came on without obvious cause, lasted three or four days, and at times were really severe and attended by a little rectal tenesmus.

The fever was altogether one of the most interesting features of the disease. It was as a rule very high—usually 103° to 104° F.; I rarely found it below 102° F. in the evenings. It was equally remarkable, however, that on several occasions it was but 99° F. in the evening. It was similar to, and as inexplicable as, that associated with leucemia and other grave anemias.

The blood changes in my case were similar to those described in the majority of reported cases. There was a moderate reduction in the number of red corpuscles, associated with a greater reduction in the percentage of hemoglobin—blood alterations commonly referred to as of the chlorotic type. In a number of the reported cases a marked leucopenia existed, but such was not present in my case. The detection of several erythroblasts and of a small number of somewhat distorted erythrocytes may also be noted.

Concerning the nature of the disease I am

unable to add anything to what has already been written on the subject. Whether the condition merits the distinction of a clinical entity; whether it is akin to pseudoleucemia, and is in reality a splenic form of the affection, as some hold; or, finally, whether it is but a peculiar form of secondary anemia, the evidence at hand does not warrant us in affirming. Whether the enlargement of the spleen is the direct cause of the anemia, or whether both of these are the result of a common etiologic factor, is at present unknown. It appears, though, from clinical observation that the enlargement of the spleen is the primary event. Whatever the nature of the affection, it presents a tolerably uniform symptomatology, and provisionally, therefore, the designation splenic anemia is satisfactory. Provisionally, also, the designation anemia with enlargement of the spleen is equally as satisfactory if not more so.

It is upon the assumption that the enlargement of the spleen is the essential feature of the disease that the only successful treatment known at present is based. Medicinal treatment is hopelessly inefficient. In but a few cases has temporary improvement followed regulation of the diet and the mode of living, fresh air and sunshine, iron, arsenic, and the like. In appropriate and selected cases removal of the enlarged spleen should be considered. The seriousness and possible fatal consequences of the operation itself must be borne in mind, and it should not be undertaken without reasonable hope of benefit to the patient. That the proper treatment be instituted at a favorable time, the endeavor should be to recognize the affection as early in its course as possible, and, if the patient be in good condition, the operation should not be delayed longer than is necessary for the physician to become assured of the correctness of the diagnosis. Operation should not be undertaken in those cases in which the patient is manifestly doomed to an early death. That satisfactory results, however, may be expected in favorable cases, is indicated by the statistics collected by Sippy. Of seven cases reported in the literature, five were cured by removal of the enlarged spleen. The remaining two died of hemorrhage. To these five successful cases Osler had added a sixth. Some doubt, however, may be expressed with regard to the certainty of the diagnosis in several of the cases collected by Sippy.

The duration and course of the disease in the individual instance should influence us in deciding for or against surgical intervention. The duration of the disease, however, is difficult to estimate, and this is in great measure dependent upon the difficulty in ascertaining the duration of the first stage—the stage preceding definite enlargement of the spleen and grave anemia. The disorder is generally said to last from six months to two or three years. Certain writers, however, have observed cases of much longer duration. Thus, Osler reports one case that lasted five years, and another that persisted for at least twelve years. Cases of rapid course are naturally unsuited for operation. Operation in these cases would not only most probably hasten the inevitable fatal termination, but it would likewise reflect discredit upon the only successful mode of treatment known at present. In those cases in which the disease is of slower course, when there occur remissions and temporary improvement under medicinal treatment, and when the patient is in fairly good general condition, the wisdom of operative intervention should be carefully considered. That in properly-selected cases, surgical treatment may be undertaken with hope of a successful outcome is indicated by the fact that in none of the successful cases so far reported was the operation performed early in the course of the disease.

SOME DIAGNOSTIC DETAILS.[1]

By WM. EDGAR DARNALL, A.B., M.D.,
OF ATLANTIC CITY, N. J.;
VISITING PHYSICIAN TO THE ATLANTIC CITY HOSPITAL; FELLOW OF THE AMERICAN ACADEMY OF MEDICINE, ETC., ETC.

THERE are many things in the art of diagnosis not to be found in text-book or journal literature, nor, indeed, anywhere else save by an earnest and observant study of the open book of Nature itself. Skilful diagnosis does not entirely consist of a dulness here, a tympany there, a thrill, a murmur, a classic group of symptoms or scientific facts as put down in some text-book. It is a notorious fact that few cases follow out in detail the text-book description of the disease. What is it, then, that makes the reputation of one physician as a skilful diagnostician, and of another as a bungler? The older physician, with a wealth of experience, has so trained his perceptive faculties that he grasps

[1] Read before the Atlantic City Academy of Medicine.

and groups the essential details of a case almost at a glance, discarding the unimportant things, some of which are often much magnified by the patient. In this respect, he has the advantage of the young practitioner, who is prone to lay too great stress on whatever symptom may be most exaggerated by the sick man. The real value of symptoms with reference to the general principles of physiology, histology and pathology must be correctly estimated by him who would excel in diagnosis. The perceptive qualities of the mind must also be highly developed, and supported by a habit of the closest observation.

Perception may be defined as that faculty of the mind by which we take instant cognizance of an object or a truth without being able to analyze or communicate the mental process by which we arrive at our knowledge; nor does ignorance of the process necessarily affect the correctness of the conclusion. Fortunate is the physician who naturally possesses this faculty in marked degree. The sense organs of such men are exceedingly keen, and their mental processes rapid. They go straight to the point, recognizing the disease at times instantly, and with almost unerring certainty. It is this faculty, coupled with the habit of unconsciously observing details—the most trivial modification of appearance, complexion, voice, manner, gait, expression, muscular control and hundreds of other minutiæ, that gives to some of our greatest men their seemingly wonderful intuitiveness in diagnosis. Of such physicians it may be said, as of poets, "They are born, not made."

In estimating the true value of symptoms with reference to disease, the mind must be able to sift the wheat from the chaff; to get at the significant things and draw from them correct inferences based on a thorough knowledge of the scientific facts of medicine. Very necessary is that particular quality of a well-trained mind known as the synthetic or syllogistic power, which grasps the salient points of any question, groups them in a logical manner, and reasons from them to a correct and positive conclusion. The true physician should be above the plane of narrow reasoning and prejudice. He must be able to view a question from many standpoints abstractly and have a mind so balanced by an innate sense of justice that each shall receive its due weight in formulating a conclusion.

No physician can see too much, nor observe too carefully. No detail is too trivial for his mental note-book. The minor things not in books may often help him. The expression of the face and the quick glance of the eye often speak volumes, and human nature itself should be thoroughly studied to correctly understand them. Who that has seen the cowering look of the opium fiend, or the cunning craftiness and deceit of the eye of the morphinomaniac, fearful of detection in his vice, can forget it? The bloated face and red eye of the alcoholic is practically pathognomonic. The contorted face, wrinkled with sharp pains; the pallid, worn and weary expression of chronic pain, suffering written in every lineament of the face; the careworn, anxious look of the mother, striving daily, bearing bravely, perchance uncomplainingly, the burden of domestic duty, faithful to her spouse and her family in spite of ovarian and uterine troubles, that are sapping her health and wrecking her nervous system; or the dusky pallor, colorless lips, pinched nose, appealing eyes, distressed and pitiable in their very glance of anxiety, as if they foreshadowed the impending calamity of unrelieved shock or dire disease; all speak with no uncertain voice in determining the conditions confronting us. The discontented and pouting expression of the spoiled hysteric, selfish, domineering, exacting sympathy from all around her, and yet unsatisfied with whatever may be done for her; the wild eye of mania and fever's delirium; the silly face of the imbecile, the exalted or depressed expression of various forms of insanity; the dull, stolid, square-jawed and empty face of the adenoid child, all mean much in diagnosis; while pitiable is the wrinkled, weazened, and very knowing, little old-woman face of the helpless, speechless infant with marasmus. This can hardly fail to impress itself on the dullest observer, when first seen.

The eye alone, dilating with pleasure or contracted with pain, its brightness or listlessnes varying in all degrees of well-being and sickness, indicates often the slightest change from a feeling of buoyancy and health to that of languor and malaise. Its lack of luster is often the first thing noticed in what the watchful mother terms "droopiness" in her child.

Together with the bright eye, red lips and flush of fever, may be seen also an incoördination of groups of muscles. The actions are quick, often jerky, the small muscles of the face twitch, the lips tremble, the voice loses its firmness and trembles as if under strong and suppressed emotion. Loss of control over the voice tone is noticed in many conditions, as in the, at times, abnormally loud laugh and spasmodic speech of the hysteric, the jerky, nervous voice, the aphonia of laryngitis, or the husky voice, the hoarse voice, the voice of hypertrophic rhinitis, which has no carrying power. The tone, expression of the voice, may distinguish the acute cry of pain and the groan of suffering from content and satisfaction. This tone language becomes often the only means of determining in the infant, whether its cry is of anger, griping pain or the fretting of general discomfort. The complexion should not go unnoticed; compare the transparent skin, beautiful flush of color and bright eye of healthful youth with that dull, deadened eye, yellowed sclera and muddy skin, in which each feature takes on a coarser and rougher appearance—the bilious picture of a circulation full of toxins that should have been excreted by lagging organs. The whole face expresses misery and dejection. There is the bumpy acne face, suggestive of genito-urinary disturbance; the tuberculous, waxy, white skin, with hollow, glittering eyes and hectic red; also the roseate nose and florid plethora of gouty grumblers, fit subjects for cerebral hemorrhage; the soft,

pasty, white skin of the victim of Bright's disease, and that the peculiar, lifeless white of the uric-acid diathesis, so well associated with the refined and physically inactive elderly ladies of the community who pride themselves on their delicate sensibilities and to whom the slightest hardship is a horror. Nor can one forget the bluish lip and peculiar bronzed appearance of the cachectic complexion of malignant disease, as if a transparent skin had been spread over brown paper. This complexion has been considered almost pathognomonic by some physicians.

Such things as the breathing and position of a patient may be indicative. The child with high fever breathes very rapidly. The respiration is also accelerated in the case of an adult. Is the breathing superficial, showing deficient lung space or abdominal pain; catchy, with intercostal neuralgia, or indicating endothelial involvement of pleura or peritoneum, or acutely-congested lung tissue; or is it the distressed breathing of the asthmatic, with its long, whistling and forced expiration? The blue-lipped laborer for breath in failing cardiac compensation; the unconscious patient pallid with alarming hemorrhage, sighing and sighing the life away; the Cheyne-Stokes type and the stertor of cerebral involvement are impressive danger signals to the close observer of disease.

Position is significant, especially with infants. Restlessness, constant shifting of position, and tossing about shows at once an excited condition of nerve-centers. It may be from fever, soreness and pain, a limiting of breathing space in the upper respiratory tract, indigestion, or nervous states. A patient lying on the back, with legs drawn up, suggests pelvic or abdominal pain, or inflammatory conditions which may be of a very varied nature. The sufferer from cholera morbus is frequently found on the side, with thigh and legs flexed, usually unquiet and writhing in pain at intervals. The position taken by those with many chronic troubles is often of the greatest importance in formulating a diagnosis. The space, however, devoted to a short paper does not permit the enumeration of more than a few of the multitudinous things that are seen every day by the observing physician as he makes his rounds from house to house. He often gathers valuable information from the bearing, gait, and even the dress of his patient.

Just a word may be said as to odors. In many diseases certain odors are prominent, as in typhoid fever, grip, tuberculosis, sepsis, decomposition, and other conditions in which elevated temperature plays a part. There are those who have gone so far as to state their ability to diagnose variola, typhoid, etc., by their odor alone. The diarrhea odor, the urinary smell, etc., are significant, while some persons on entering a room where there are several women can single out by the sense of smell those who are menstruating or suffering from leucorrhea.

A very valuable thing in treatment, as well as in diagnosis, is a correct appreciation of temperament. Temperaments may be divided into four general classes *viz.*, (*a*) the nervous; (*b*) the sanguine; (*c*) the bilious, and (*d*) the phlegmatic. Individuals not conforming exactly to these classes are invariably found to be modifications of them or combinations of different classes, as neuro-sanguine, neuro-bilious, sanguino-phlegmatic, or bilious-phlegmatic.

The typical nervous temperament is of brunette description and slender build. Persons of this type are quick-thinking, quick-acting; every movement of the body is nimble and alert. They are always active, both mentally and physically, and keyed to such tension that everything concerning them, joy and sorrow, pleasure or pain, is acute and intense. Highly imaginative, they are often worrying over the things that never happen, and many of this type are burning their supply of life's fuel constantly at a white heat as long as it lasts.

The sanguine temperament, usually of healthy organization, is possessed of much endurance, but needs also much rest and sleep. As a rule, individuals of this type have sandy hair, clear skin, but are sometimes portly in build. This type, perhaps, is every bit as quick and active as the nervous in many ways, yet takes life more calmly and just as it comes. It is not so intense. The sanguine man is not an extremist. He is an optimist, seeing the good in things, looking on the brighter side of questions depressing to others, philosophizing out the results and quietly awaiting their materialization. He has a keen appreciation of the ridiculous, enjoys life in an equable way, and doesn't let its cares and trials weigh so much on his spirits as to depress him and affect his health.

The bilious type, black-haired, dark-skinned, angular, rugged, strong in principle and decision of character, often "grand, gloomy and peculiar," is subject to fits of the deepest despondency and melancholia. These people are matter-of-fact, take life very seriously, and shoulder as a duty, with the heroism of martyrs, weighty responsibilities, from which more timid characters shrink. Some of the world's greatest leaders are numbered among this class, a typical example of which was Abraham Lincoln.

Every one recognizes in the thick-set, broad-shouldered, short-necked, broad-jawed and ruddy man all that is expressed in the word phlegmatic. This type is slow to think, slow to act, slow in his movements, but dogged in determination, often what is known as "pig-headed" and obstinate. Every question must filter through his mind, drop by drop, until the conclusion is reached, while the opposite and more fickle, nervous type has seen through it at a glance and perhaps changed his mind two or three times in the meanwhile. The phlegmatic man enjoys none of that keenness and intensity of feeling experienced by the nervous or sanguine type, nor do the pleasures of intellectual pursuits and high culture appeal to him. The coarser fiber of his make-up demands rather the satisfaction of physical enjoyment. His tastes tend toward the sensual, and he is often lazy, dull and heavy.

A physician may so familiarize himself with in-

dividual physical types and combinations of temperament, when once his attention has been given to the matter, that at a glance he can tell from the color of the hair, the texture of the skin, the firmness of the flesh, appearance of mucous membranes, expression, bearing, general build, and similar indications, just what allowance should be made for sensitiveness and reactionary power. Such considerations, no doubt, influence every practising physician more or less, perhaps unconsciously, in many cases, in making up his mind with regard to the general condition of his patient.

I have not sought to exhaust such a broad subject in a short paper, but only to touch on a few things here and there that might suggest others met with in your various experiences, and to emphasize the importance of noting every detail, even the smallest and most trivial, in the matter of diagnosis. Such details often aid materially the grouping of things in a general analysis of the patient's tendencies and susceptibilities, and will well repay the close and careful observation given to their study.

ON GONORRHEAL CYSTITIS IN THE FEMALE.

By F. BIERHOFF, M.D.,
OF NEW YORK;
FORMER ASSISTANT, DEPARTMENT OF GENITO-URINARY DISEASES, BERLINER ALLGEMEINE POLIKLINIK; FORMER ASSISTANT GYNECOLOGICAL POLIKLINIK OF DR. R. KNORR, BERLIN, GERMANY.

Since Wertheim in 1894 proved that a pure, gonorrheal cystitis does exist, a number of other authors have reported cases of this sort, but still investigations upon this subject have been far fewer than the frequency (though often unrecognized) of this condition would warrant. Krogius[1], in the examination of 22 cases of primary and secondary cystitis, found the gonococcus of Neisser twice, in one of the cases in pure culture. Rovzing[2] reports four cases in which, by means of the cystoscope, he diagnosed a cystitis in the turbid, acid urine of which he found the gonococcus, in one case accompanied by the Bacterium coli. Rostoski[3] found three in the examination of 120 cases of cystitis reported in medical literature. So also Melchior[4] states that true gonorrheal cystitides may occur, which are caused by the gonococcus of Neisser. According to Finger's statement[5], it is to be counted among the rarest of the complications of gonorrhea; Barlow[6] says that cystitis is seldom a direct complication of gonorrhea, but is to be traced back to the intervention of other irritating agencies, a point of view with which Zuckerkandl[7] agrees. Bumm[8] takes the position that every cystitis occurring in the female under these conditions is due to a mixed infection. Young[9] reports two cases of acute and two of chronic gonorrheal cystitis, and states that he believes that this disease is more frequent than is reported. With this statement I fully agree, though I cannot accept all of his cases without question as being cases of gonorrheal cystitis. A careful examination of his article leads me to believe that, although Case I. (in which he obtained the gonococcus in pure culture) was a cystitis, it is far more likely that Case II. was an acute gonorrheal prostatitis (a number of cases similar to the above which have come under my personal observation lead me to take this view), although he did obtain by aspiration purulent urine which contained typical gonococci. Similarly I am led to believe that his cases of chronic gonorrheal cystitis (the one said to be of five years' duration) were not cystitis but prostatitis. Careful examination of a large number of acute and chronic cases of gonorrheal prostatitis has shown me that these may often simulate an acute or subacute cystitis, both as regards the degree of tenesmus and the degree of the turbidity of the urine. It is to be regretted that in none of his cases could the author give us absolute certainty as to the involvement or non-involvement of the bladder, by performing cystoscopy. Without this measure, or the opening of the bladder, no diagnosis can be absolutely certain in the male, owing, as above remarked, to the possible involvement of the prostate. In view of the danger of this procedure, however, in acute cases, and of the exceeding sensitiveness of the urethra, it is a step which may not be taken during the acute stage, though I am of the opinion that during the chronic stage, if proper antigonorrheic precautions are taken, the danger will not be as great as is believed.

In the female, however, in whom there is no prostate gland to complicate the picture, the diagnosis is a much easier matter. The cystoscopic examination of a number of cases of gonorrheal urethritis and urethrocystitis has convinced me that, while there may be some burning pain during urination, in the course of a urethritis, tenesmus, and increased frequency of urination, as well as turbidity of the second urine (the first being allowed to escape through the catheter), will not occur until the gonorrheal inflammation has involved the sphincter or this and the bladder itself. Hence I cannot agree with Kolischer's[10] view that the diagnosis of gonorrheal cystitis in the female can only be made with the aid of the cystoscope, though, in view of the comparatively harmless nature of this procedure, I have felt justified in using it as an aid to diagnosis and as a means of obtaining greater certainty, especially in order to be sure as to the portion of the bladder involved and the extent of the involvement—of course, in every case, under proper precautions.

The results of my examinations were as follows:

Total number of cases of cystitis examined	92
In these there was present	
Cystitis catarrhalis in	67
Cystitis suppurativa in	25
The cases of gonorrheal cystitis were found only among those of the suppurative type, and were in number. Of these the form of cystitis was	5
Cystitis colli in	4
Cystitis universalis	1

The symptoms of the condition are those of an acute or subacute suppurative cystitis; that is, increased frequency of urination, accompanied by a greater or less marked degree of burning and cutting pain during urination and also preceded or

followed by a degree of tenesmus varying with the extent of involvement of the sphincter and the tissues in its immediate neighborhood. At times the urine contains small quantities of blood, which usually appears toward the end of urination. Fever or chill may also occur. The urine is usually of acid reaction and turbid, the turbidity being due to the presence of pus-corpuscles and a few epithelia. The gonococcus is found both intra- and extracellular in the urinary sediment, and has the typical characteristics of the gonococcus of Neisser. Where any doubt exists Gram's method of differential staining must be employed. As the culture of the gonococcus from urine is acknowledged to be a most difficult matter, the coincidence of the micro-organisms found in the urinary sediment and the urethral discharge may be taken as sufficiently conclusive. In case of need a culture may be made, with far greater chances of success, from the urethral discharge. The cystoscope finally adds the certainty of the presence of a vesical inflammation and its extent and degree of severity.

But, while there is usually the history of an accompanying urethral, or vaginal discharge, the nature of which the microscope reveals, and while the symptoms are usually marked, my examinations have shown me in many instances that the discharge may be so slight as to escape any but the most careful examination, and that only after close questioning may one elicit any physical symptoms whatever. I have in several instances only had my attention called to the bladder by the patient. The nature of the cystitis was what led to a subsequent examination of the urethra.

In view of the difficulty of getting the gonococcus to grow in cultures made from urine, I did not deem it necessary to try to obtain them in my cases; but the diagnosis of gonorrheal cystitis was only made when turbid second urine was obtained (the first being allowed to flow off through the sterilized catheter after careful irrigation of the urethra with protargol solution), the turbidity being then proven to be due to pus-cells, many of which contained intracellular diplococci presenting all the morphological characteristics of the gonococcus of Neisser. When any doubt existed, Gram's method was applied.

The accounts of the pathological changes and cystoscopic picture vary decidedly with different authors. Finger, Ghon and Schlagenhaufer[11] found, in a case of subacute gonorrheal cystitis examined by them, swelling and reddening of the mucous membrane; the epithelium was desquamated down to the deepest layers and easily removable. There was present in the subepithelial connective tissue an infiltration consisting of round cells, spindle cells and leucocytes: the capillaries, also, were distended, reaching at many points nearly to the epithelium, and were filled with leucocytes. Gonococci were present in small numbers in the upper layers of the subepithelial connective tissue. Wertheim[12] found a true gonorrheal thrombophlebitis of the capillaries of the vesical mucous membrane, with gonococci upon and between the epithelial cells, in pus-cells in the subepithelial connective tissue, and also in the capillaries of this tissue, which they filled. Finger[13] states that "we find the bladder, according to the intensity and extent of the process, in toto or at different points, more or less swollen, more or less intensely inflamed, or only crossed by dilated, dendritic vessels. The epithelium is loosened from its base in shreds, which in part continue to be attached by threads to the mucous membrane, in part float free in the urine, whilst the swollen follicles appear as dark red points." In the four cases reported by Rovzing[14], all of which occurred in the male, cystoscopy showed, in the first case, the mucous membrane at the fundus to be markedly reddened, thickened and succulent, the redness gradually growing less marked toward the periphery. At the vertex the redness was only slight. In the second case diffuse injection and swelling of the entire mucous membrane were found; in the third, the entire mucous membrane was reddened and swollen, the process being most marked in the neighborhood of the internal urethral orifice; in the fourth it was markedly injected at the fundus and the region of the sphincter, while the rest of the bladder was slightly but diffusely reddened. Casper[15] expresses his opposition to cystoscopy, in acute gonorrheal cystitis, and accepts Finger's description. In the case reported by Wertheim[16] the wall of the bladder, viewed through an endoscopic tube, was found to be diffusely reddened, laid in folds, and tending easily to hemorrhage. Zuckerkandl[17] found in a case of severe gonorrheal cystitis, in which he opened the bladder by incision, the wall thickened, the mucous membrane of an even, purplish-red tint, lying in stiff folds, nowhere detachable, and bleeding easily. In the lighter forms, he says, one only sees a diffuse, increased ramification of the blood-vessels which, more marked at points, causes a macular reddening of the mucous membrane; he states that, at times, we find a true cystitis colli. According to Kolischer[18], we find in recent inflammations the mucous membrane, either in the neighborhood of the internal orifice or over the entire surface of the bladder, covered with discrete (inselförmig), pale-red spots, between which the mucous membrane appears fully normal. According to his views the discrete type of the inflammatory areas is characteristic for gonorrhea of the bladder, although, in chronic cases the process tends to spread, the color of the originally red spots becoming more or less brown, the process even going on to the formation of ulcerations.

In the five cases described below the diagnosis of gonorrheal cystitis was in each made only after careful examination of the urine and after cystoscopy. In none of them, as also in a number of other cases of gonorrheal urethritis examined, was there the least increase in the severity, or any spreading of the condition, as a result of the instrumentation, even though these patients could only be treated as ambulant cases. As a result, I should not hesitate to employ the cystoscope in such cases in future, using, of course, similar precautions. I hold it to be especially necessary in

such examinations to avoid cauterization of the mucous membrane.

The first case coincided in type with that mentioned by Kolischer, many of the areas, however, being of a dark red, almost brown color, others lighter. That the cystoscopic picture did not agree with that given by the other authors I consider to be due to the fact that the case came under our care early, and that we were at once enabled to make a correct diagnosis, to begin promptly appropriate treatment, and thus check the spread of the inflammation. I am inclined, therefore, to accept the "discrete" form as the type of the inflammation in cystitis corporis in the early stages, whereas, in the older cases, the process may tend to become a general, suppurative inflammation through the spreading and final confluence of the inflammatory zones. It seems likely, also, that in this type the infection of the body of the bladder occurs, not through the contact of the walls of the bladder, nor through the urine itself, but solely through the blood-vessels and lymphatics.

The other four cases presented the cystoscopic picture of a cystitis colli suppurativa: The entire circumference of the internal orifice was found to be inflamed, the mucous membrane being swollen

Fig. 1.—Papillomatous growths at and near the sphincter vesicæ in a case of cystitis gonorrhoica.

and thrown into irregular papillomatous folds, having lost its glistening appearance, and bleeding very easily. In one case (Case II.), in which I also succeeded in obtaining endovesical photographs (see Figs. 1 and 2), the lumen of the internal urethral orifice was encroached upon by two papillomatous, inflamed, tumor-like masses. The patient, a primipara, had recently been confined and had subsequently been infected by her husband. I believe that the extent of the changes was, in this case, greatly increased as a result of the bruising of the tissues of the urethra, the child's head having, in passing, crushed it against the pubic arch. Thus the gonococci had an opportunity to penetrate much more deeply into the tissues. In one of the other cases, also, there was a distinct oedema bullosum at the periphery of the inflammatory zone.

All five of the cases added a further proof of the truth of Rovzing's view that gonorrheal cystitides belong to the class "cystitis suppurativa acida." The histories of the cases were as follows:

CASE I.*—Urethritis gonorrhoica, cystitis gonorrhoica; vulvitis gonorrhoica; endometritis non-gonorrhoica. March 10, 1900. Frau G., divorced three and one-half years ago; one abortion. The patient has for a long time had a leucorrheal discharge; for three days, however, she has noticed an increase in the discharge, also pain and burning during micturition, and that she must urinate

Fig. 2.—Similar but larger growth on the opposite side of sphincteral margin.

about every quarter-hour during the day; during the night, however, she does not urinate. The present condition has not been treated nor examined up to the present. Vulvar and urethral discharge is purulent and contains typical intracellular gonococci. None in vaginal secretion. Following irrigation of the urethra with about 50 c.c. of a ½ per cent. protargol solution, the urine is drawn off by means of a sterilized metallic catheter, the first being allowed to flow off, the second caught in a clean, glass vessel and immediately examined.

Urine.—Turbid, acid, contains albumin. Sediment consists exclusively of red blood-cells and pus-cells, many of the latter containing typical, intracellular gonococci. No other micro-organisms present.

Cystoscopy.—The mucous membrane of the entire bladder-wall is strewn with small round, hemorrhagic points and nodules, which strongly resemble a purpura, but are somewhat raised above the level of the surrounding mucous membrane. Between these points, or zones, the surface appears perfectly normal. In the neighborhood of the sphincter the process is most marked.

Therapy.—After preceding irrigation of the urethra with a ½-per-cent. protargol solution, about 75 c.c. of this fluid were injected directly through the urethra (without a catheter) into the bladder, and allowed to remain there until the next urination. After cleansing the vulva and irrigating the vagina with the same solution, a gauze strip, saturated with a 5-per-cent. solution of protargol in glycerin and water, was inserted into the vagina, filling this and being allowed to protrude

*Reported in the Dermatologische Zeitschrift, Vol. VII., No. 3.

therefrom and a part to rest between the labia. This strip remained in place for twenty-four hours. Warm Sitz-baths daily. No internal treatment whatever was employed, except regulation of the diet. The treatment was repeated daily.

March 15th.—Symptoms during urination have disappeared. The patient now urinates every two and a half to three hours. Treatment has caused no pain whatever. Urine normal. Cystoscopy shows decided improvement.

March 17th.—Cystoscopy shows bladder entirely normal.

March 26th.—Urethral secretion contains isolated pus-cells, many squamous epithelia, no gonococci, but other bacteria (chiefly diplobacilli). Patient has not been either treated nor examined for some days because of menstruation.

April 5th.—Since above date no symptoms whatever. Treatment has been continued. On stripping the urethra a mere trace of mucous discharge is obtained. This consists almost exclusively of mucus, large, squamous epithelia, isolated, degenerated pus-cells, no micro-organisms whatsoever. Urine normal. Cystoscopy shows bladder-walls entirely normal.

The alcohol test and menstruation having produced no reaction, the patient was discharged cured.

Case II.—Urethritis gonorrhoica; cystitis colli gonorrhoica; vulvitis gonorrhoica. Frau S., 27 years of age, married ten months, primipara (confinement nine weeks ago), no history of previous discharge. April 20, 1900. Patient complained of discharge, accompanied by frequent and painful urination, and pain in abdomen. Examination reveals purulent discharge at vulva and from urethra. Urethral orifice markedly reddened and swollen. Discharge has been present for about two weeks. First coitus after confinement over two weeks ago; again four or five days later. Four days following the latter patient noticed some discharge. This had been preceded for some days by burning about the genitals and burning pain upon urination. Husband admits having contracted gonorrhea about eight days after his wife's confinement. We were able later (June) to verify this, as the husband was still uncured, and, by proper treatment, to cure him also.

Urethral Discharge.—Purulent, pus-cells contain intra- and extracellular gonococci. Gram's stain positive. No other bacteria.

Urine.—After irrigation of the urethra with sublimate solution followed by protargol in ½-per-cent. solution, the urine is drawn off as described in Case I. It is markedly turbid, of acid reaction, grows more turbid on boiling and on addition of acetic acid. Sediment consists of pus-cells and many intra- and extracellular gonococci. Gram's stain positive. No other bacteria.

Cystoscopic Examination.—The entire sphincteral margin is markedly inflamed and swollen, especially at the lower portion. At the lower, lateral angles there are two large, inflamed, papilloma like tumor masses. (See Figs. 1 and 2.) Trigone edematous and strongly congested. The rest of the bladder entirely normal.

Therapy.—Precisely the same as in Case I.

April 23d.—Urinates now six times during the day and once at night (but the latter only if awakened by the child). Neither pain nor tenesmus on urination. Discharge diminished. Still contains gonococci.

April 24th.—Cystoscopy shows little change discoverable. Symptoms diminishing.

April 28th.—Symptoms have disappeared. Discharge very slight; this still contained yesterday a few isolated gonococci.

Cystoscopy shows decided improvement. The swelling and inflammation have become decidedly less marked.

May 3d.—Urine still slightly turbid. Cystoscopy shows continued improvement.

Therapy.—In addition to former measures a trial injection of about 50 c.c. of a ⅛ per cent. solution of nitrate of silver into the bladder is made. Patient is ordered to use daily, a vaginal irrigation of two liters of a 1-1200 solution of nitrate of silver in place of the tampon.

May 5th.—Gonococci still present in the urethral secretion and in the sediment of the still turbid urine.

May 8th.—Cystoscopy shows that the tumor upon right side has disappeared; that upon left side decidedly decreased in prominence.

May 10th.—Gonococci still present in small number in the urethral discharge and in the urinary sediment.

May 18th.—General condition normal. Trace of turbidity of the urine. Sediment contains no gonococci. Still some purulent vulvovaginal secretion. Cystoscopy shows condition similar to that of the 8th inst.

May 22d.—Increase in discharge, which still contains isolated gonococci. Woman admits coitus with her still uncured husband.

Therapy.—Protargol increased to 2 per cent. Vaginal irrigation of nitrate solution replaced by gauze tampon, as before.

May 25th.—Decided improvement.

May 29th.—No symptoms whatever. Urine normal. Cystoscopy shows bladder normal with exception of a trace of swelling and redness on the left margin of the sphincter. No urethral discharge. Vulvovaginal discharge very slight. Alcohol test; coitus test (husband to wear condom).

June 1st.—After above tests a trace of discharge containing isolated extracellular diplococci. Therapy as above.

June 7th.—No urethral discharge. Urethral scraping shows epithelia, solitary, degenerated pus cells; is free of micro-organisms. Urine normal. Cystoscopy shows bladder normal, with exception of slight hyperemia at trigone. Test irrigation with 150 c.c. of ⅛-per-cent. nitrate of silver solution.

June 9th.—No urethral or vulvovaginal discharge. Scraping shows only epithelia; free of micro-organisms. Vaginal scraping shows only epithelia; no micro-organisms. Cervical scraping, mucus containing isolated pus-cells and epithelia; no micro-organisms. Urine entirely clear. Sedi-

ment only a trace; consists of isolated epithelia and degenerated leucocytes. No micro-organisms.

Therapy.—Since the 1st inst. no protargol has been used. Patient is now instructed to live as usual, and to use daily vaginal irrigation of warm water.

June 16th.—In spite of absence of treatment, and although patient has drunk beer and has several times indulged in coitus (husband wearing condom), there is no reaction whatever. Urethral scraping epithelial in character. Urine normal. Cystoscopy shows bladder normal. Discharged cured, but requested to report from time to time as her husband is still suffering from a subacute gonorrhea.

June 23d.—No symptoms whatever; no discharge.

June 26th.—Condition normal. Cystoscopy shows bladder normal.

July 19th.—Condition normal. Urethral scraping purely epithelial. Urine normal. Cystoscopy shows bladder normal. Discharged cured.

Case III.—Urethritis gonorrhoica; cystitis colli gonorrhoica; bartholinitis sinistra gonorrhoica. Frl. S.; twenty-five years of age; no history of previous discharge. June 16th: For the past eight days complains of having to urinate about every quarter-hour during the day, the act being accompanied by burning and tenesmus, and followed by slight bleeding. During the night sleep is not disturbed. Patient admits having had coitus twelve days ago. Urethral orifice and left labium inflamed and swollen. Vagina shows no inflammatory changes. Erosion of cervix present. Urine is turbid and of acid reaction. Urethral secretion is purulent; contains typical intra- and extracellular gonococci. No other micro-organisms. Discharge from bartholinian gland is purulent; contains gonococci; no other micro-organisms. Vaginal scraping contains epithelium, diplobacilli, no gonococci. Cervical secretion is of mucous character; contains diplobacilli and diplococci (not gonococci, however). Urinary sediment contains pus cells, many containing typical intracellular gonococci.

Cystoscopy.—Sphincteral margin inflamed and swollen, especially at the lower, left portion. Trigone markedly hyperemic. Oedema bullosum vesicles visible at different points, near the zone of inflammation. Blood clot in left pocket of bladder. Body of bladder free.

Therapy.—Same as in Case I., with addition of massage of the infected gland. Complete treatment could not be begun until the 19th inst.

June 20th.—Symptoms have somewhat lessened in severity.

June 21st.—Urinates now only every two hours during the day. Pain and tenesmus have diminished in severity. Discharge less marked; still contains gonococci, but fewer. Still purulent secretion from the diseased gland. Cervical secretion mucous in character; contains a few pus cells, but no micro-organisms whatever. Cystoscopy shows no marked change.

June 30th.—Has not appeared for further treatment. Discharged improved.

Case IV.—Urethritis gonorrhoica; cystitis colli gonorrhoica. Frl. N.; twenty-two years of age; no history of previous discharge. June 23d: Patient complains of having noticed some discharge since about the 9th inst. Since the 15th she has had some cutting and burning pain on urination, but no tenesmus. Yesterday noticed some blood at the end of micturition. Frequency normal. Admits having had coitus on the 1st inst. Inspection reveals redness and swelling (not very marked, however), of urethral orifice. Vulva and vagina show no inflammatory changes. Urine, turbid, acid. Urethral discharge, purulent; intra- and extracellular gonococci (Gram positive). No other micro-organisms. Urinary sediment, pus cells; intra- and extracellular gonococci (Gram-positive). No other micro-organisms. Cervical secretion, mere trace; mucous character; no gonococci; other bacteria, however.

Cystoscopy.—Inflammation and swelling at sphincteral margin and trigone. Body of bladder free.

Therapy.—Same as in Case I.

June 25th.—Urination normal. Urine still turbid. Urethral secretion less; gonococci present. Vaginal secretion contains epithelia and bacteria, but no pus cells or gonococci. Cervical secretion mucous in character and free of micro-organisms.

June 26th.—Discharge diminishing; urine clearer. Still gonococci. In addition to above treatment, a small strip of gauze saturated with a 5-percent. protargol solution is laid into the urethra. This is repeated daily.

June 28th.—Symptoms disappeared. No discharge. Urine clearer. Urethral scraping shows gonococci, but in small number.

June 30th.—Discharge and gonococci increased. Patient admits having disobeyed orders and having drank weiss bier during entire course of illness. Cystoscopy shows still decided inflammatory changes.

July 3d.—Diminution in discharge and in number of gonococci. Urine clearer. Sediment contains degenerated pus cells and isolated gonococci.

July 5th.—No symptoms. No discharge. Scraping contains pus-cells, epithelia, mucin and isolated gonococci.

July 6.—Urine clear. Sediment normal, and contains no gonococci. Urethral scraping free of gonococci. Cystoscopy shows still some redness in the neighborhood of the sphincter.

July 7th.—A few gonococci in the urethral scraping.

July 9th.—Urethral scraping free of gonococci.

July 10th.—Urine continues normal. In urethral scraping are a few gonococci.

July 11th.—Urine normal, sediment free of any micro-organisms. Urethral scraping also free.

July 12th.—Menstruation, consequently no treatment. Must leave the city to go home to parents. Discharged improved.

Case V.—Urethritis gonorrhoica; cystitis colli gonorrhoica. Frau G., thirty-two years of age.

June 30, 1900. Complains of discharge from genitals which has lasted about three weeks. Has to urinate nearly every half hour, the act being accompanied by burning. Is not disturbed during night. Patient states that she was infected by her husband, who admits extramatrimonial infection. Discharge comes from urethra, which is swollen and reddened. Neither vulva nor vagina shows inflammatory changes. Urethral discharge purulent. Intra- and extracellular gonococci. No other micro-organisms. Urine, turbid; acid. In sediment, pus cells with intra- and extracellular gonococci. No other micro-organisms.

Cystoscopy.—Sphincter and trigone inflamed and swollen. At upper right angle of sphincter a broad, papilloma-like growth of the size of a pea.

Therapy.—Same as in Case I.

July 7th.—Still gonococci in urethral discharge, though fewer in number.

July 9th.—Symptoms have entirely disappeared and urination is normal in character. Still many gonococci in the urethral secretion. Urine almost clear. Sediment consists of degenerated pus cells and epithelia. No micro-organisms.

July 11th.—Still gonococci present. Patient admits having drunk weiss-bier.

July 14th.—Still gonococci in the urinary sediment and in the urethral discharge.

July 19th.—Slight discharge, containing degenerated pus cells and isolated gonococci. Urine clear. Only a slight trace of sediment obtainable, consisting of degenerated pus cells and epithelia. No micro-organisms.

July 20th.—Scraping of the urethra, as also the minimal urinary sediment still contain isolated gonococci. Urine entirely clear.

July 21st.—Still some discharge. Free of gonococci, however. Cystoscopy shows still inflammation and swelling of trigone and lower margin of sphincter. Referred to Berliner Allgemeine Poliklinik for continuation of treatment as this clinic closes for the season.

Although, in the male, as before stated, one must hesitate before performing cystoscopy during the course of a gonorrhea, I believe that the above five histories have demonstrated that the dangers of this procedure are not so great in the female, provided, of course, that the examination is preceded and followed by appropriate measures. The additional knowledge of the case which we gain overbalances, I think, the slight danger. In every case of acid cystitis, however, before any treatment is begun at all, I should strongly recommend the microscopic examination of the sediment. If this be done, I feel certain that we shall hear from the gynecologists, in the future, of far more cases of true gonorrheal cystitis than we have up to the present.

A final word concerning the treatment. In former days, before we possessed agents which destroy the gonococcus wherever it may be reached, without unduly irritating the mucous membrane, it was the custom to treat the acute stage of gonorrhea by letting it alone and contenting oneself with keeping the patient as quiet as possible and by putting him or her on internal treatment designed to keep the urine bland and unirritating. This plan, in but too many cases, proved its utter inadequacy. At present, since we possess—notably in protargol and largin—two reliable preparations which, if properly used, will do all that drugs can do, we are not justified in delaying the commencement of treatment for one day. This view, the truth of which I have had ample opportunity to prove, is gradually being accepted by even the more conservative of scientific observers. Finger[19], formerly one of the most ardent adherents of the expectant form of treatment, now places himself firmly upon the opposite platform. At his side are Frank[20] and Fuerst[21], who also speak for the immediate institution of the treatment. I believe with them that if we use the non-irritant, non-astringent antiseptics, we can achieve the best result by beginning our treatment at the earliest possible moment. So that in cases of gonorrheal cystitis, beside restriction of diet and the use of frequent hot Sitz-baths, we may begin the use of such remedies, in appropriate strength, in the form of urethral and vesical irrigations, some of the solution being allowed to remain in the bladder each time, these being made in the male without the use of a catheter. In the female the plan which we employed seems to me to offer the best chances of success. It is of interest to note that in all of our cases we were enabled to prevent the spread of the disease beyond the parts originally infected.

One may not, however, discharge a case as cured until the urethral discharge has entirely disappeared and remains away even after the different provocative tests (in the female also until after menstruation) have been employed, until the urethral scrapings are epithelial in character and entirely free from gonococci, until the urine is entirely clear and the sediment normal and free of gonococci, and until the cystoscope reveals a vesical mucous membrane free of all traces of inflammation.

In conclusion I wish to express my most sincere thanks to my friend and colleague, Dr. Richard Knorr, of Berlin, Germany, for the permission to study and report these cases.

CLINICAL MEMORANDA.

SEVERE ACUTE PLEURISY, FOLLOWED BY PHLEBITIS; DEATH FROM EMBOLISM.

By CHARLES ROSS JACKSON, M.D.,
OF NEW YORK;
INSTRUCTOR IN GENERAL MEDICINE AND DISEASES OF THE CHEST IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; ATTENDING PHYSICIAN TO THE NORTHWESTERN DISPENSARY.

THE patient, a small woman, sixty-three years of age, had been for three days suffering greatly from dyspnea and pain in the left side when I first saw her. On this occasion her respiration was 62, pulse 140, and feeble, and temperature 102° F. Examination showed the heart apex to be in the fourth space on the right side in the nipple line, and the left chest to be entirely filled with fluid. The left lung was so misplaced that respiratory sounds were not audible anywhere on this side, not even at the apex.

The patient was also suffering from a large intra-abdominal tumor, which protruded beneath the umbilicus as a nodular mass. This tumor was hard and resistant in most of its extent, and was very large, occupying almost the entire abdominal cavity. The great size of the abdomen had been referred by the patient to a dropsical condition. Fluid was not demonstrable, however, and the kidneys were normal. Later, after operation, I was able to determine that the heart was normal. There was no edema of the legs. An exploratory puncture of the left side of the chest revealed the presence of a clear, serous fluid, but owing to reluctance on the part of the patient, I was unable to operate for its removal until the next day, the second after my first visit. Then, with the assistance of Dr. D. T. Marshall, I removed 127 ounces of fluid. At the time of operation the pulse was 140, temperature 101° F., and respiration 64; cyanosis was marked. Hypodermatic stimulation was necessary after the removal of but a few ounces, but as the pulse rallied respiration became slower and the general condition improved. There was not any severe cough during the operation, and the left lung expanded well as the fluid was withdrawn.

After aspiration the heart was found to have swung back to nearly its normal position. The puncture was made in the seventh space in the mid-axillary line, the patient being in a semi-recumbent dorsal position, partly because this was the most comfortable for her, and also because I believed that this position would secure a more uniform and gentle return of the heart to the left side, and would prevent undue or sudden traction on its supporting blood-vessels above—a very important consideration in massive left-sided pleurisy in old persons.

Half an hour after operation, the pulse was full and strong at 108, and respiration 36. As only a small amount of fluid had been left in the chest, it was entirely absorbed in a few days under tonics and mild purgatives. On the fourth day the pulse had fallen to 80, the temperature was normal, and the respiration 28; the left lung had expanded in a very satisfactory manner, and the pleura showed but slight signs of thickening. To my mind the still rapid respiration was due in some degree to upward pressure by the tumor in the abdomen.

The patient was up and about on the fourteenth day; her condition was good, the pulse not exceeding 90 after exercise, and its volume being excellent. On the twentieth day she had one degree of fever, and for several days there was an afternoon rise to 101° F. Repeated exploratory punctures did not reveal any evidence of empyema, and the physical signs in the chest were negative. On the twenty-fourth day she complained of pain and great tenderness in the calf of the left leg, also of chilly sensations, although the temperature did not exceed 101° F. The pain increased, the leg became very edematous, and the popliteal vein could be felt as a hard cord; cord-like masses also could be felt along the course of the internal saphenous vein. At the same time the patient complained of severe pain over the femoral, where there was also great tenderness. Absolute rest was enjoined, the limb was elevated, and other means taken to combat the phlebitis. One week later the tenderness had diminished, the limb was still edematous and cyanotic to an unusual degree, but the temperature was again normal and the general condition good. I carefully cautioned the patient and her attendants, enjoining absolute quietude of the limb. On the morning of the thirty-sixth day after operation I saw her, and found her condition good, heart action excellent and no evidences of lung or pleural trouble. The leg was progressing favorably, and the temperature was normal. The next day, despite all warnings, the patient got up, walked two or three steps and returned to bed. She was immediately seized with an agonizing pain in the right side of the chest, and great dyspnea. I saw her a few minutes afterward, and found her cyanosed and struggling for breath. The heart was weak at 150, respiration variable, about 60 and very shallow. Death, which followed rapidly, was preceded by most intense cyanosis.

The sudden onset of pain in the chest, after exercising and the mode of death make it certain that there was an occlusion of the pulmonary artery. In the absence of any chest trouble at the time of death and in view of the severe phlebitis of the leg, we are safe, I think, in ascribing the death to an embolus from the diseased vein rather than to the formation of a local thrombus in the pulmonary artery.

Aside from the mode of death, the case is interesting because of (1) the amount of fluid removed from the chest and manifestly due to acute pleurisy, and (2) the development of a phlebitis after simple pleurisy—a rare occurrence. In the absence of autopsy the relation of the abdominal tumor to the phlebitis is purely conjectural. That by its size and pressure it disturbed the circulation in the leg, and thereby aided in the formation of thrombus is very probable.

CASE OF DEXTROCARDIA.

BY HOMER M. THOMAS, A.M., M.D.,
OF CHICAGO.

A CONSIDERATION of the general subject of heart displacement reveals two varieties, namely, those which are congenital and those which are acquired. Considering the type of acquired displacements, under which head comes the case I am about to report, we find that very considerable displacement of the apex beat to the right may be due to retraction of the right lung from fibroid phthisis. Again, a very common cause is found in the development of pneumothorax. In cases of fibroid phthisis in which dextrocardia exists, the apex beat is frequently above the right nipple, and might be recognized by physical signs dependent upon collapse or fibrosis of the lung. The heart is pressed out of position by effusions of fluid—inflammatory, serous or bloody—into either pleural cavity; by pneumothorax of either side; by intrathoracic tumors; by hypertrophic emphysema or other causes of enlargement of the lungs; by extensive pneumonic consolidation; or by abundant pericardial effusion of any kind. Certain conditions of the abdominal contents produce a similar effect, for example, gaseous distention of the stomach and intestines; enlargement of the liver and other solid organs; abdominal tumors of all kinds and ascites when considerable. In displacements of the heart toward the right the condition is usually the result of effusion into the left pleural cavity, of contracting processes of the right lung or pleura, of left pneumothorax, and of tumors of the left side of the chest or of the mediastinum. In extreme cases the heart may be displaced toward the right side until the impulse is found in the axillary region.

The case here presented is that of F. J., aged forty-six years, occupation rubber worker, whose duties involved the inhalation of considerable quantities of soapstone as well as carbon bisulphide. There is no family history of tuberculosis nor of his having had pneumonia or pleurisy. His only sickness of recent date was an acute rheumatism in 1895. Present condition reveals cough, shortness of breath which began seven years ago; has had much headache and pain in left chest throughout his illness; for two years the cough was very dry; at present expectoration is abundant and comes in somewhat paroxysmal seizures. No tubercle bacilli have been found. The injection of tuberculin developed absolutely no reaction.

Physical Examination.—General anemia, some debility, dyspnea. Complexion dark; emaciation moderate. Form of chest, bulging at costochondral junction; respiratory movements hurried; restricted intercostal retraction. Apex beat fifth space, right nipple line; upper border, upper edge fifth rib; right border, anterior axillary line; left border, right border sternum; lower border, contiguous with the liver.

Mensuration.—Height, five feet, eight inches; weight, 124 pounds.

Measurement.	Expiration	Inspiration.	Difference
Right lung	17½	18	½
Left lung	16¾	17	¼
Combined	34¼	35	¾

Morning temperature, 97.5° F.; noon, 98° F.; evening, 98° F. Frequency of pulse, 92; rhythm regular. Heart, valvular sounds clear; arteries show moderate thickening.

Upon percussion of the left lung anteriorly dulness is found extending from the supraclavicular, clavicular and infraclavicular regions. Upon the right lung anteriorly there is hyperresonance, extending from the lower border of the first rib down to the lower border of the third rib in a semicircular line about one inch to the right of the costosternal articulation. Posteriorly, the lower border of the right lung shows increasing dulness extending from the lower border of the eleventh rib up to the inferior border of the sixth rib posteriorly. Posteriorly in the right lung, extending downward from the superior border of the fourth rib, down to the eight rib anteriorly, there is found typical bronchial breathing with moist, fine, bubbling râles, and increased vocal fremitus.

Diagnosis.—Our conclusions, based upon the history, as well as upon the present physical findings, are that this is a case of acquired dextrocardia, due to fibroid phthisis and an antecedent attack of pleuropericarditis.

Treatment.—Remove the exciting cause of the dextrocardia, and, necessarily, the displacement will tend to correct itself. This general principle of treatment can be applied to only a limited extent in this individual case. The exciting cause is of too chronic a character, and the lesions resulting from the same too permanent to admit of entire removal. Treatment is, therefore, mainly directed toward the maintenance of the best possible physical condition and the relief of acute symptoms as they may arise.

703 Field Annex.

MEDICAL PROGRESS.

Modification of Cow's Milk.—Of the various methods employed for rendering milk suitable for the infant, most are defective and do not prevent the precipitation of casein in heavy curds in the stomach. L. VON DUNGEN (*Münch. med. Woch.*, Nov. 27, 1900) recommends a very simple method which renders cow's milk perfectly digestible for the youngest patient. The milk, previously boiled, is heated to body temperature and then coagulated with rennet. The coagulum is then completely broken up with a beater. The suspension will eventually be so fine that the finished product can hardly be distinguished from the unaltered milk. Extended experiments have shown this method to be preferred to the usual addition of cereals which infants do not always take well, or to the preliminary digestion with pancreatin which alters the milk to an undesirable degree.

Muscular Atrophy in Infancy.—Muscular atrophy, according to J. HOFFMANN (*Münch. med. Woch.*, Nov. 27, 1900) can be divided into muscu-

lar, neural and spinal. The latter, of distinct familiar and hereditary type, though rare, especially claims the author's attention on account of the ease with which it can often be diagnosed *intra vitam*. It presents the following peculiarities: Usually children, who are born of healthy parents and without the aid of the forceps and whose first months of life have not differed from those of other infants, are attacked by the disease between their fifth and ninth months. In the course of weeks or months the motions in the hips become more and more weak, and this without the appearance of any acute symptoms of infection, such as vomiting, diarrhea or convulsions. Walking, if it has already been begun, will become impossible. At the same time, or soon after, a weakness of the dorsal and abdominal musculature manifests itself. Subsequent months or years show the progress of the disease to the upper extremities and neck, so that eventually the entire system of muscles is more or less paralyzed. The cranial nerves, with the sole exception of the spinal part of the accessorius, are not involved. Atrophy of the muscles, which may be hidden by a well-developed fatty deposit in the subcutaneous tissues, reaction of degeneration, loss of patellar reflex, contracture and a kyphoscoliotic curvature of the spine are found. On the other hand, the mental faculties and sensation are rarely affected, except for occasional transient pains. A cure is impossible despite the free use of saline baths, strychnine, phosphorus, the iodides, electricity and quinine; death from pulmonary complications invariably occurs in from 1-4 years. Bulbar symptoms or muscular hypertrophy or pseudohypertrophy have not been observed. Pathologically there is a symmetrical degeneration of the neurons of all nerves below the hyperglossal, of the multipolar ganglion cells of the anterior horns and of the intra- and extramedullary portions of the anterior roots. The brain and the white columns of the cord are unchanged. The cause of the disease is unknown, but is probably due to an inherited weakness of the parts involved.

Varicose Veins.—A cure of this condition has been attempted in recent years by two methods of operation: (1) Ligation of the veins in several places, with or without the removal of small sections, or (2) excision of a considerable portion of the vessel in continuity. J. B. BLAKE (*Boston Med. and Surg. Jour.*, Dec. 13, 1900) reports 11 cases, of which number 7 were cured by operation, 3 were relieved temporarily or partially, and 1 was worse than before. The case of the patient who reported himself as worse than before is reported in detail as illustrating a type in which the operation by excision will probably be followed by little or no improvement. Of the 3 patients who were partially or temporarily relieved, 1 reported no pain but a small ulcer, 1 still had some pain, and in 1 the pains returned at the end of a year. The ages of those reported cured varied from twenty-five to fifty years. In all cases the scars were firm, not tender and not painful. Blake draws the following conclusions: (1) Operation for radical cure of varicose veins by dissection is not successful in every case. (2) To obtain successful results, cases must be selected and certain conditions avoided and recommended to palliative treatment. (3) The condition which will probably militate against satisfactory results are: (*a*) Old age, or an extremely debilitated condition; (*b*) excessive and very extensive varicosity; (*c*) occupations which to an extraordinary degree favor the development of varicose veins. (4) Cases which may be cured by a thorough and careful operation are: (*a*) Local varix, even of marked prominence, particularly if thrombosis has occurred, either in thigh or leg; (*b*) extensive varix, limited to a single venous stem; (*c*) varicosities, which are a bar to passing civil service, military or naval examinations; (*d*) cases in youth and middle life; (*e*) cases in which the development of the permanent varicosity was at least partially due to more or less removable conditions, such as flatfoot, garters, etc. (5) Operation, even if not entirely successful, will usually relieve such complications as thrombosis, hemorrhage and ulceration. (6) The usual conditions which follow unsuccessful operations are: (*a*) Pain in and around the scar (*b*) general swelling and tenderness of the leg; (*c*) development of varicosities above or below the operation scar, but not at the site of the operation itself. (7) In all operated cases, general systematic treatment, as well as local treatment, should be prescribed, together with exercise and the avoidance of a continued upright position whenever possible. (8) Cure of symptoms does not necessarily mean the removal of all visible varicosities. (9) Comparison of relative methods of multiple ligation and continuous dissection must be based upon a larger number of cases than here recorded. (10) Bennett's conclusions and his extreme limitation of the indication for successful operation are too sweeping.

Tetany Following Intoxication.—F. DAMMER (*Münch. med. Woch.*, Nov. 13, 1900) reports the case of a patient who was treated with male fern and calomel for tapeworm and who, soon after the expulsion of the head developed typical symptoms of tetany with both Trousseau's and Chovstek's symptoms present. Since the ordinary causes of tetany were absent and since calomel has never been known to cause tetany, it was but proper to ascribe this to intoxication with male fern, which not rarely causes nervous symptoms of a less-pronounced character.

Oxyurides in the Skin.—P. BARRAGALLO (*Gaz. Degli Ospcd e dc Clin.*, No. 111, 1900) records the case of a boy, aged fourteen, whose previous history was negative, complaining of intense itching about the anus. This had become so intolerable that the scratching of the part by the patient's finger-nails had produced an eroded, inflamed area about the anus, which local applications of various ointments failed to relieve. About the anus there were excoriations, and rhagades, which were intensely painful, so much so as to interfere with the patient's locomotion and with his ability to sit comfortably. These symptoms had continued so long that the boy's health began to show impairment. The region about the anus was reddened and ex-

coriated and covered with a seromucous exudate, in which, especially in the discharge from the rhagades and excoriations, were found small, round, mobile, whitish, elongated bodies, about six millimeters long, which on microscopic examination proved to be *oxyurides*; some of these parasites were found in the stools, also ova in various states of development. A diagnosis of *oxuriasis cutanea* having been made, the following decoction was given: Senna leaves, one-half ounce; water enough to make a decoction of two and one-half ounces; to this add sodium sulphate, two drams, and simple syrup, five drams. This was divided into two parts, and taken with one day intervening. External treatment consisted of soothing salves to the excoriated area and the injection twice daily of a three-quart enema of a 1-1000 salicylate-of-sodium solution, made with sterilized water; at the end of a fortnight all evidence of these worms had disappeared and from this time on the patient convalesced nicely without interruption.

A Case of Hematuric Bronzed Disease.—An interesting report upon this uncommon disease, with the history of a case, has recently been contributed by NOBECOURT and MERKLEN (*Archives de Médecine des Enfants,* November, 1900). Beginning shortly after birth, the patient shows more or less jaundice, sometimes the color being almost black, with accompanying cyanosis of the face and extremities. The urine is usually scanty and contains blood. Abnormal temperature is more common than fever. Death frequently takes place in three or four days. The post-mortem shows the blood to be almost black; the liver is markedly congested with no obstruction to free passage of bile anywhere. The kidneys present multiple hemorrhages, most marked in the cortex; the uriniferous tubules also contain red blood-cells. Concerning the etiological side nothing definite can be said; it is usually regarded by many as infectious in character, although no special micro-organism has yet been associated with the disease. The case reported by the authors was that of an infant, ten days old, apparently born under natural conditions. From the first the infant showed icterus, cyanosis and subnormal temperature. It died three hours after birth. The autopsy findings of interest were mainly limited to the kidneys. The liver was bile-stained, but otherwise normal; the kidneys showed exterior hemorrhages in both the cortical and medullary portions. The bacteriological examination was considered negative.

Heroin Hydrochloride.—BERNARD LAZARUS (*Boston Med. and Surg. Jour.,* Dec. 13, 1900) calls attention to the stimulating effect of heroin upon the respiratory centers, its sedative action in conditions of irritation, its freedom from depressing action upon the heart or circulation, and its analgesic properties, as ascertained by various observers. He has studied the action of the drug in fifty-two cases, nine of which he reports in detail to illustrate its action in various diseases of the air-passages as well as in other conditions. These fifty-two were cases of pulmonary tuberculosis, bronchitis, asthma, pneumonia, laryngitis, coryza, rhinitis and intercostal neuralgia. The writer used the hydrochloride of heroin because of its solubility in water, which property heroin itself does not possess. Under the administration of heroin hydrochloride the relief of pain, cough and dyspnea was obtained in all cases in from one to five days. Nausea and giddiness followed the administration of heroin hydrochloride in only two of the fifty-two cases. This happened after a dose of one-sixth grain, and promptly disappeared after the dose was reduced to one-twelfth grain. In one case the drug produced a gastric disturbance similar to that caused by morphine taken on an empty stomach, but this was not noticed when the drug was given after meals. Constipation resulted in three cases, but was easily relieved by adding a small dose of calomel to each dose of heroin hydrochloride. The bad effects only followed the larger dose of one-sixth grain and promptly disappeared on reducing the dose to one-twelfth grain. In most of the cases the dose given was one-twelfth grain of heroin hydrochloride every two to four hours, according to the severity of the symptoms. From a study of his cases Lazarus considers heroin hydrochloride a valuable drug, and he would rank it as a specific in pulmonary affections accompanied by cough. While in neuralgia its analgesic qualities, and in asthma and whooping-cough its anti-spasmodic effect should give it an important place in the treatment of these diseases.

Menstruation in the New-Born.—DR. KOUINDJY of Paris read a very interesting report of three cases of menstruation in newly-born children (*Archives de Médecine des Enfants,* November, 1900). So rare has this been that Naegelé considered vaginal hemorrhage in this class of patients to be a myth; however, the author states that some isolated reports have been published by Underwood, Billard, Ollivier, Bovain, and a few others. In 1876 Dr. Cullingmont is said to have presented to the Manchester Obstetrical Society a report of some 32 collected cases. The 3 cases of Dr. Kouindjy were observed during the last three years. Two of the cases were healthy children born to the same mother, a sanguinous discharge appearing on the fourth and fifth days, respectively, after birth; the third case, likewise well built, had a similar vaginal discharge on the fourth day after birth. The writer finds that opinion is by no means uniform with regard to the interpretation of these hemorrhages. For some the discharge is the result of some lesion in the genital tract; others, on the other hand, like Camerer, believe that the bleeding is the result of disturbances in the pelvic circulation induced by a hurried ligation of the cord. A few like Ollivier, Pinard and the author, fancy that many are genuine instances of precocious menstruation.

Lichen Planus of the Urethra.—Lichen planus occurs quite frequently upon the oral mucous membrane and cases have been described in which the larynx and the anus were involved. A unique case, however, is that of E. HEUSS (*Monatshft. f. prokt.*

Dermatolog., Nov. 15, 1900). He had under treatment a patient affected with lichen planus of the mouth. A constant irritation in the urethra led to a urethroscopic examination with the result that another patch was detected in the middle of the penile portion. The administration of arsenic for two months resulted in a complete cure.

An Antemetic.—Following the anesthesia of ether and chloroform nausea and vomiting have come to be considered almost the rule and, although frequently favorably influenced by various methods, they are seldom entirely controlled. L. J. HIRSCHMAN (*N. Y. Med. Jour.*, Dec. 15, 1900) has recently observed thirty cases in which he has administered 10 to 15 grains of chloretone about one-half hour before the anesthetic is given. It is preferably given dry on the tongue and followed by a little warm water. The amount of anesthetic used was diminished from one-third to one-half. None of the patients was nauseated during the operation, only ten per cent. were nauseated afterward, and only one vomited more than twice after coming out of the influence. The drug is supposed to be both a local anesthetic to the mucous membrane and a sedative to the nervous system.

Enlarged Malarial Spleen Treated Hypodermatically.—V. PIGA (*Gaz. Degli Osped e de Clin.*, No. 111, 1900) records the case of an eighteen-year-old lad, in whom, in addition to quinine treatment, he employed injections of an iodine-potassium-iodide solution, after the following formula:

Potassium iodide.....	2.0	(ʒ ss)
Iodine pure.....	1.0	(gr. xv)
Distilled sterilized water..	100.0	(ʒ iii ss)

About thirty minims of this solution was injected, at first twice daily, then once daily and finally every other day until at the end of seven weeks the spleen was no longer to be felt and all pain in the left hypochondriac region, which from the beginning of the disease had been most painful, had disappeared.

Subjective Symptoms of Neurasthenia.—Among the most alarming and disagreeable symptoms of neurasthenia, L. HOEFLMAYR (*Münch. med. Woch.*, Nov. 13, 1900) mentions those due to irritation of the vagus. The physician is usually called at night to see the patient, who, struggling with extreme dyspnea and cardiac pain, seems to be in the last stages of an organic heart lesion. Cold perspiration usually covers the entire body; the lower extremities feel cold, and the pulse is increased in frequency and often arhythmic, though not weak. A history of constipation can usually be elicited and a large dose of castor oil usually brings relief, so that it is probable that the symptoms are due to irritation of the end-filaments of the vagus in the intestines through gases of putrefaction. The whole process seems to be a defence on the part of the body to limit self-intoxication. The characteristic headache is another very common and disagreeable symptom of nervous exhaustion which may also find an explanation in auto-intoxication. This is also relieved by the liberal use of cathartics.

THERAPEUTIC HINTS.

Ihle's Paste.—For inflammatory and parasitic skin diseases the formula is:

℞ Resorcin.....	0.7	(gr. x)
Starch		
Zinc. oxid.....		
Lanolin		
Vaselin.....aa	8.0	(ʒ ij)

Morphinism.—If the drug be suddenly withdrawn, writes Gilman Thompson, severe gastro-intestinal and cardiac symptoms may follow. Therefore gradually reduce the quantity, so that it may be omitted after two weeks. Meanwhile give strychine and digitalis in full doses, and warm baths or hot packs to quiet restlessness. The vegetable astringents catechu and kino will control diarrhea. Milk, eggs, broths, custards, and other assimilable foods, should be given every two or three hours. The patient requires moral support, restraint and close observation for a long period.—*Practical Medicine.*

Mumps.—Even mild cases require rest in bed, writes Jules Comby, as prophylaxis against complications. Fatigue favors the development of orchitis. A milk diet, a purgative such as calomel, scammony, jalap, or a Seidlitz powder, the external application of opium-and-belladona ointment, and the spraying of nose and throat with boiled water or a solution of boric acid or naphtol constitute the treatment of mild cases. Counterirritation, continuous cold, and massage, are not recommended. In severe cases cool baths at 64° to 68° F., three or four times a day, with acetate of ammonia, strychnine, caffeine, or quinine, reduce the temperature and promote comfort. Orchitis requires rest and emollient applications, the active treatment by massage, leeches, blisters, etc., often resulting in atrophy. For the deafness following mumps, potassium iodide, quinine, and pilocarpine are advised. For the nervous symptoms, the wet sheet, bromides, musk and ether. Where a grave anemia persists the indications are iron, quinine, cod-liver oil, iodotannic syrup, etc., and change of air, with perhaps a course of sea baths.—*Twentieth Century Practice.*

Gastric Cancer.—The problem, write William Osler and T. B. McCrae, is to nourish an individual with impaired gastric functions. Food should be given in small amounts, concentrated, and very digestible. Liquids should be given sparingly, the great thirst being relieved by hot water half an hour before meals and by enemata. Milk, raw or modified, is mostly borne well in small amounts, especially if salt is added. Soups, meat extracts, finely-minced, tender meats, eggs and stewed fruits are helpful, carbohydrates promote fermentation, and are limited in amount; the coarser vegetables and the fats should be omitted. The indulgence of special longings gratifies the patient. When necessary nutrient enemata may be given. As stomachic, condurango with hydrochloric acid is beneficial, and

quassia, gentian, calumba, or nux vomica may be used. Hydrochloric acid and pepsin promote digestion. Good whiskey taken neat or with apollinaris or soda-water is helpful. Lavage is indicated in cases with motor insufficiency, especially if there is dilatation. Hemorrhage and ulceration are no contra-indication, and the washing removes adherent decomposing and irritating material. As a general tonic arsenic usually does best, and:

℞ Ac. carbol. vel creosot.....0.065 (♏ j)
Tinct. iodi.....0.13 (♏ ij)
Glycerin.....4.0 (ʒ j)

will allay fermentation. Lavage is best at bedtime and at least four hours after a meal. It may be performed with plain water or solutions of boric acid, thymol, salicylic acid, or sodium bicarbonate. —*Cancer of the Stomach.*

Vaginismus.—Remove local cause such as inflamed hymen, irritable urethral caruncle or caruncul\u00e6 myrtiformes, fissures or inflammations. Fissures of the hymen are best treated with four-per-cent. chloral hydrate applications; fissures of the bladder-neck by overdistention with strong nitrate of silver and bougies left to melt in the urethra, of:

℞ Cocain\u00e6 Hydrochlor.....0.75 (gr. xij)
Ol. theobrom .....q. s.

Div. in bacilli, No. xij, and insert one morning and evening. The general treatment consists of warm hip-baths, iodoform, gram 0.3 (gr. v), suppositories, atropine ointment, gram 0.12-30.0 (gr. ij-ʒ j), and the application twice a week of silver nitrate, gram 0.7-30 (gr. x-ʒ j), to vulva and hymen. Gymnastics, horseback-riding, bicycling, hydrotherapy, cheerful company, and avoidance of attempts at sexual intercourse tend to remove the abnormal sensitiveness. If these methods fail, the vaginal entrance is forcibly distended under anesthesia, and subsequently a glass plug is inserted morning and evening for a couple of hours.—*Garrigues in Diseases of Women.*

Whooping-Cough.—Da Costa preferred quinine sulphate in full doses or chloral with or without bromides and a spray of sodium bromide, gram 1.3 to 30.0 (gr. xx-ʒ i), with gram 0.12 (♏ ij) of fluid-extract of belladonna added. The paroxysms are lessened in severity by:

℞ Codein\u00e6 sulph.....0.06 (gr. j)
Ac. carbolic.....0.5 (♏ viij)
Syrupus.....15.0 (ʒ ss)
Glycerin.....30.0 (ʒ i)
Syr. limonis.....15.0 (ʒ ss)

Sig.: One tablespoonful every two or three hours. Keating uses a spray of:

℞ Ammon. bromid.
Potass. bromid.....aa. 4.0 (ʒ i)
Tinct. bellad.....4.0 (ʒ i)
Glycerin.....30.0 (ʒ i)
Aq. rosæ, q. s.....ad. 120.0 (ʒ iv)

The diet regulated, the clothing warm, and open-air exercise are advisable.—*Hughes in Practice of Medicine.*

Chronic Gastritis.—A strict dietetic regimen, writes Gilman Thompson, must be carried out faithfully for two or three weeks, and it is important to give minute details in writing. Meals should be regular and preceded and followed by half an hour's rest lying down, and the food must be slowly and well masticated. For severe cases milk is recommended, six to eight ounces, with vichy or soda-water and salt added, every two and a half or three hours. If there is much nausea add cerium oxalate, gram 0.2 (gr. iij), and sodium bicarbonate, gram 0.35-0.7 (gr. v-x), to each feeding. If undigested curds appear in the stools the milk should be lessened in quantity or temporarily peptonized. Some patients digest best boiled milk or buttermilk. The milk may be supplemented by fresh meat-juice, scraped beef, white of egg, and granum. Less severe cases do best on a meat diet of lean roast beef, tender rare beefsteak, chops or roast mutton with dry toast or stale bread, and a minimum of butter. Boiled rice baked potato, spinach, shredded wheat, toasted soda crackers, thin dry gingersnaps, granose, zwieback, baked apples, orange-juice, baked custard, and plain blanc-mange are all digestible, eggs, soft-cooked or raw, are borne well by some, and the soft parts of raw or stewed oysters. Foods to be prohibited are fried foods, twice-cooked meats, the coarser vegetables, sweets, pastry, cakes, puddings, and strong condiments. Omit drinking with meals. Kumyss, black coffee, hot water, beef extract or bouillon with hot water, should be taken when thirsty, and water, hot or cold, not iced, should be taken freely on retiring, on rising, and several times during the day. Moderate outdoor exercise and daily sponge-bathing with cool water, followed by friction, are to be advised when suitable. If there is a lack of gastric juice hydrochloric acid, gram 1.3 (♏ xx), may be given immediately after meals, and pepsin, gram 0.35-0.7 (gr. v-x), may be added. Pancreatin and soda bicarbonate, aa. gram 1.0 (gr. xv), half an hour after meals, and silver nitrate, gram 0.008 (gr. 1/8), in obstinate cases, are recommended. Nux vomica tincture, gram 0.7 (♏ x), may be given with gram 4.0 (ʒ j) of tinctures of gentian, cinchona, or cardamom before meals. Constipation requires podophyllin, gram 0.006 (gr. 1/10), cascara, or sodium phosphate or sulphate. Lavage is of value. In obstinate cases use a two-per-cent. alum solution; for fermentation three-per-cent. boric acid, and for mucus, five-per-cent. sodium-bicarbonate solution. In lieu of lavage, hot alkaline water taken before each meal will dislodge mucus and wash the stomach contents into the bowel.—*Practical Medicine.*

Alopecia.—When this is dependent on general morbid conditions, an exciting lotion is:

℞ Pilocarp. mur.....0.50 (gr. viij)
Ol. gaultheri.
Ol. santali.....aa. gtt. 5 (gtt. v)
Tinct. cantharid.
Glycerin.
Spt. camph.....5.0 (grs. lxxv)
Alcohol.....80.0 (ʒ iiss)

Rub lightly into scalp once a day.—*Brocq in Jour. de Med. de Bordeaux.*

BELLEVUE MEDICAL BOARD AND THE INVESTIGATIONS.

The disclosures of disgraceful mismanagement in the administration of municipal hospitals has culminated in Bellevue's recent scandal. The abuse of patients, extortions from the poor, neglect and cruelty, are only what one might expect in an institution where every non-medical appointment is obtained through "pull," and where, it is hinted, "influence," as well as merit, is necessary for the well-being and comfort of every one within its walls. We know that every large municipal hospital in the country, the good angels of which are politicians, suffers from some of the abuses that have made Bellevue's name scandalous. But what we are not prepared for is to find Commissioner Keller, in his energetic newspaper reform, laying some of the burden of mismanagement on the medical staff. We hope that it is merely accidental that, in wielding his unaccustomed scourge, he has let the lash fall upon the men who have in spite of difficulties served Bellevue so well.

The Medical Board of Bellevue is one of the best that can be found in any hospital in this country. Its members have seen the abuses, the deficiencies, the mismanagement, at every turn; they have complained, they have protested, they have expostulated. In reply they have received promises, and with these they have had to be content.

Every physician on the Board, as well as the staff, has learned, after all his efforts at reform have been ignored, that just so much red-tape must be used in order to give the vendors of red-tape a livelihood. Therefore he has submitted to the methods in order to get what was necessary for his patients. If, in order to be sure that his patient would get an ounce of whiskey, he has been obliged to order a pint, he has ordered the pint. The amazing thing is that the physicians connected with Bellevue should have been able to do such good work against such odds.

And yet a slur is now thrown against them for having, as it were, connived at deeds of mismanagement. If they knew what was going on why did they keep silence? Of course they knew. What physician connected with Bellevue does not know the state of affairs there? But they have spoken, and have learned that they might as well try to move a mountain.

Once more we reiterate the belief that the proper mode of governing this large hospital, with its important dependencies, is by means of the trustee system, as proposed by the new Charter Revision. May this city see an early inauguration of this system.

CYCLIC ALBUMINURIA.

Since Cotugno demonstrated albumin in the urine of dropsical patients in 1770 for the first time, but more especially from the time when Richard Bright, more than half a century later, showed the association of albuminuria with lesions of the kidney, the significance of the relationship implied has remained scarcely unchanged through an entire medical generation. With the last few years, however, medical opinion has somewhat shifted from its original attitude and newer outlooks have abundantly widened the narrow confines of past and cherished interpretations. To many, even at the present time, the persistent presence of albuminuria is irrevocably associated with organic disease of the kidneys.

Gradually, as closer attention to detail and more perfected technic brought forward results scarcely reconcilable with older views, a few were disposed to hold themselves aloof for the traditional beliefs. The justness of such a position has been repeatedly shown in the numerous contributions of Pavy, Senator, Granger Stewart, Leube, Teissier and a host of others.

Under many conditions it has been shown that albumin may be present apart from any existence of permanent renal lesion or acute febrile disease. The influence of strong emotions, intellectual fatigue, cold bath, etc., is a point in question; the observations of Hwass based on the examinations of more than 600 healthy soldiers clearly enough demonstrate how muscular fatigue induces the elimination of albumin for short periods. MacFarlane has again shown this in his interesting studies of the urines of football players; for twenty-four hours or more after the games the urines of these players contained not only large amounts of albumin, but numerous casts, hyaline and granular. Some like Possner have even gone so far as to state that albumin may be found in the urine of everyone; these observations amount probably to no more than that by special methods a minute amount of albumin may be detected in everyone's urine. This, however, is not what is meant by the clinical term albuminuria.

A paper on the cyclic albuminuria of adolescence, recently published by Dauchez, of Paris, will renew the interest of many on this condition to which Pavy, Teissier, and Merley have given some of their best efforts. This rather uncommon and really little-understood affection begins usually in adolescence or early adult life, being most common in boys. In some cases heredity has been shown to play an important part; and often enough the existence of cyclic albuminuria is only accidentally discovered, as in a medical examination for life insurance. Whilst some have suffered from nervousness, headache, languor, dyspepsia, and anemia, many have been strong individuals in apparently perfect health. The albuminuria is essentially intermittent, being present often only during certain times of the day. On the whole, it may be said that the albumin is not detectable, by the usual tests, in the morning; then as the day goes on the albumin appears with the approach of midday, and thereafter becomes somewhat less during the rest of the day, and sometimes entirely disappears. The position of these individuals seems to be a very important factor in the determination of the albumin elimination. If they are kept in bed during the day the albumin disappears; some exceptions to this have, however, been noted by a few observers. Casts may or may not be found; hyaline casts are not unusual, but granular casts have only occasionally been observed. These cases go on for months, or years, in this condition at the end of which time the albumin has frequently been shown to disappear, leaving the individuals apparently no worse off than others. Pavy has mentioned one case in which the intermittent albuminuria continued from youth up to the forty-third year.

The existence of these phenomena as a distinct clinical type is no longer questioned by those who have had much experience in this class of affections; most of the discussions relate to the probable pathology of the condition. Two different views are at present held by clinicians regarding the side of the question. A certain group, among them Labadie-Lagrave, recognize under the name cyclic albuminuria of adolescence a type of disease in which no true nephritis can be demonstrated; others like Lecorché and Talamon do not accept this view but believe in the existence of a partial nephritis. Critical study of this form of albuminuria certainly shows that some cases grouped under this heading are truly dependent on localized or slowly-progressing nephritis, on the other hand, investigation establishes indubitably the occurrence of a cyclic albuminuria without any evidences of tangible kidney changes other than those embodied in albuminous degeneration—a finding certainly not in itself sufficient to warrant classifying under the heading of nephritis as that term is ordinarily understood in pathology. The fact remains that all albuminuria must be regarded as pathological; to speak of it as physiological is a misnomer. It is no more physiological than a heart murmur of anemia. Evidence tends to show that cyclic albuminuria is inevitably the result of some disturbance of the normal cell activity; in some patients it is nephritis, in others the lesion is of much lesser magnitude.

The wealth of opportunities for further studies has already appealed to some investigating minds and interesting conclusions will probably not be long in forthcoming from more than one source. The practical importance of the whole question is no better shown than in its relations to life insurance.

A CHAPTER IN MEDICINE.

Exactly twenty-one years ago the second edition of Bristowe's excellent Practice of Medicine was issued. In it the author says: "It would seem, then, that neither heat, water, nor decomposing organic matter is alone capable of evolving the malarious poison." "The miasm may be carried by the wind," "is absorbed in its passage across water." "Is it a gas, is it some decomposing organic substance, is it a living thing?"

Just one year later, in 1880, Laveran saw the plasmodium malariæ in the red blood corpuscles

of malarious patients in Algiers. Since that first definite observation the malarial plasmodia have been found in the red blood corpuscles of malarious patients everywhere throughout the world, thus establishing one great factor in the etiology—universality of the cause wherever the disease exists.

Nine years later Golgi differentiated two varieties of this plasmodium which differed not only in the form of the mature spherules but also in the length of time required for their sporulation—in this corresponding to the difference in periodicity of the two types, tertian and quartan agree, which require two and three days respectively for their recurrence.

A few months afterwards the "aestivo-autumnal," or crescent, form of the plasmodium was discovered and was found to be the cause of the most dangerous, or "tropical," form of malaria.

Laveran had noticed "flagellated" bodies which he regarded as especially active forms of this parasite. These Manson conceived to be spores for reproduction through mosquitoes feeding on the blood possessing them. This theory of Manson has been confirmed by the microscopical and other investigations of Major Ronald Ross in India. He found pigmented parasites in the stomach muscles of mosquitoes fed on malarious subjects, and invariably he failed to find these parasites there in mosquitoes fed on healthy or non-malarious subjects. The Anopheles was found to be the particular mosquito, preferably the Anopheles claviger, never the Culex.

Dr. MacCallum of Johns Hopkins found the flagellate bodies of the halteridium fertilizing the more granular blood corpuscles of the crow's blood in the manner of conjugation, producing thus a body containing pigment which he called a vermiculus, capable of penetrating the stomach muscle of the mosquito and thus accounting for Ross's pigment bodies there found.

MacCallum had seen this conjugation in the crescentic human form. Grassi and Koch had confirmed this observation. Thus sporulation and conjugation were both methods of reproduction of the parasite.

Christophers and Stephens found that blackwater fever was a special form of tropical malaria. Dr. Elliott protected himself in Nigeria from malaria by warding off mosquitoes. Drs. Sambon and Low have lived through a malarial season in Ostia, the most deadly region of the Italian Campagna, without taking malaria, merely protecting themselves by netting from the night-prowling Anopheles, whilst their windows were left open to the night air. Meanwhile all others resident near them, but unprotected from mosquitoes, were without exception attacked by malaria. Finally the tertian malaria has been produced in the healthy son of Dr. Patrick Manson in England by having him bit by mosquitoes sent from Italy for that purpose after they had been fed on malarious subjects.

Koch found in Africa that natives acquired a certain immunity, that this immunity was less in their children and that whites unused to malaria were peculiarly susceptible to its invasion when bitten by mosquitoes that had fed on natives in a malarious neighborhood and that quinine was a perfect prophylactic.

Here, then, is a well-rounded chapter in medical research whose value as definite scientific knowledge in its applicability to one of the most widespread of diseases, cannot be overestimated. No better illustration could be given of the progressive character of scientific medicine in the nineteenth century. Nor could a better illustration be given of the fact which is becoming more evident as time goes on, that we owe our best and most enduring advances not to any one man alone, but to the associated labors of many.

ECHOES AND NEWS.

NEW YORK.

College of Physicians and Surgeons.—Dr. James D. Voorhees of the class of '93, has just been appointed secretary of the Faculty of the College of Physicians and Surgeons.

Kings County Medical Association.—At the last regular meeting of this Association, held January 8th, Dr. L. Grant Baldwin showed specimens of uterine fibroids and Dr. Louis C. Ager read a paper on "What Determines the Real Value of Medical Papers?"

New York State Journal of Medicine.—This is the title of a new monthly periodical to be devoted to the interests of the New York State Medical Association. The chairman of its editorial committee is Dr. James Hawley Burtenshaw. We predict a useful and long life for the new endeavor.

Blackmail Protection.—A bill for the protection of physicians and surgeons from blackmail and unjust malpractice suits is also to be introduced this session. Its most important provision will be the requirement of a bond from any one bringing a suit against a physician for alleged malpractice. This bond is to be forfeited in case the judgment goes against him. This idea is based on a somewhat similar provision in English law.

Typhoid at Cortland.—This city is the center of an epidemic of typhoid fever. The city hospital is full of patients and the management is compelled to turn applicants away. Physicians are powerless and many factories and business houses are crippled because of the illness of their employees. The cause of the epidemic has not yet been determined.

Death From Strychnine.—An inmate of the Montefiore Home, forty-two years old, is reported to have died there rather suddenly last week after taking a dose of strychnine sulphate prescribed by one of the doctors for influenza. The patient had locomotor ataxia and the dose given him is said to have been $^1/_{30}$ of a gram. This dose, ½ grain, if correctly reported, is sufficient to cause death. The man died two hours after it was administered.

Antivaccinationist Inquiry.—President Michael C. Murphy of the Health Board last week began proceedings against Dr. Montague R. Leverson of Fort Hamilton and President of the Anti-Compulsory Vaccination League, who says he has been treating cases of smallpox without reporting them. Col. Murphy had two affidavits made by men who heard Dr. Leverson make the statements in regard to his treating of smallpox. As the matter stands now, Dr. Leverson's simple statement is not sufficient, it is believed, legally to hold him. He will be called upon to retract or formally affirm the statement. In the former case, the Health Board will feel satisfied, but in the latter the Board will take immediate action. It is a criminal offense not to report cases of contagious diseases to the authorities.

Grip Epidemic.—There are hundreds of cases of grip in Albany, and that this epidemic of influenza will have more than its usual run in New York City and throughout New York State this year is evidenced by the reports received so far by the State Board of Health. Since the inception of the epidemic, in 1889, it has caused about 52,000 deaths in this State. During the first year 5000 people died of it. This was increased to 8000 in 1891 and in 1892, after which years the death-rate from this cause decreased each year to 2500 in 1898-99. The State health authorities then thought it had had its run and were surprised at its general prevalence in 1899-1900, when it caused nearly 12,000 deaths, starting in with 600 in December, 1000 in January, 1250 in February, 3500 in April, 1500 in May, 400 in June.

Tuberculous Meat.—Twenty-five carloads of tuberculous cattle have passed through or have been shipped from West Albany to New York City within the past ten days. How many head of diseased cattle have found their way into the New York City market during the recent fall months the State authorities do not pretend to estimate. A special report upon this carload was made to the State Agricultural Department by one of its inspectors, who has been operating at the West Albany Cattle Yards for several weeks past. This inspection was instituted to discover violations of the bob veal law, and the disclosures which resulted otherwise were of a startling nature. It is during the fall that the farmers weed out undesirable cattle, and agents scour the country for such animals, offering nominal prices. The carload mentioned is a sample of what has been going into New York City for some weeks to be made into bologna sausage, though the "best" cuts find a resting-place upon the butcher's block.

Coming Medical Legislation.—More than two hundred bills relating to medicine are introduced into the Legislature at every session. The recommendation of the Charter Revision Commission that a physician may hold the office of President of the Board of Health in this city is regarded by medical men as of great importance. At the last session of the Legislature a bill making a similar amendment to the charter of the greater city received the endorsement of the State Medical Society, and that body, as well as the Association, will use its influence again this year in favor of the revised charter provision. As most of the questions dealt with by the Health Board in its regular routine are medical questions, a doctor who acts from his own knowledge can often be more efficient than a layman who has to depend upon others for expert advice.

Midwife Regulation.—A new bill for the licensing and regulation of midwives is another which will be pushed. As will be remembered, the bill introduced last year by Senator Plunkitt for the same purpose passed Senate and Assembly, and was signed by the Mayor. Gov. Roosevelt, however, withheld his signature. The new bill, it is understood, will differ from the old chiefly in that it designates the Board of Regents of the State of New York, instead of the City Board of Health, as the body intrusted with the prescribing of regulation, the conduct of examinations, and the issuing of licenses. This change, it is said, removes the cause which kept the Governor from signing the bill last year. It is thought safer to vest the large discretionary powers in the Regents than in a possibly Tammanyized board appointed from among the sanitary inspectors. Many doctors think it out of the question to abolish midwives entirely, but it is hoped that by a rigid examination ignorant and criminal women can be driven out of the profession and its standard gradually raised. At present licenses are granted to midwives by the Board of Health on the recommendation of two physicians.

Gouverneur Hospital Open.—The new Gouverneur Hospital building at the foot of Gouverneur Street was thrown open to the public last week for inspection. There was no formal ceremony, but about five hundred persons took advantage of the opportunity to make a tour of the hospital. The building is four stories high, of brick, has a frontage of 125 feet and extends back about 175 feet. With its equipments it cost $200,000. The decorations are of white enamel,

even to the chairs, which lends a very bright aspect to the interior. The building is fireproof and everything in it is of the latest design. The hospital will begin to receive patients this week, when the patients in the old hospital will be transferred to the new one. On the first floor of the building is the office, the doctor's reception room and the medical board room. There is also the accident ward and the children's ward, which contains twelve cots. The male medical ward has twenty-eight beds and is on the second floor. The nurses' bedrooms, sitting-room and head nurse's room are also on this floor. On the third floor is the male surgical ward. This has accommodations for twenty-six patients. The operating-, receiving- and sterilizing-rooms are on the top floor, with the women's ward, which has twenty-four beds, the kitchen and laundry.

Expert Testimony and Legislation.—Some sort of bill will doubtless be introduced regarding the regulation of medical expert testimony in the courts, and possibly for the licensing of experts. The reintroduction of last year's bill requiring the use of a certain type of bottle for the putting up of poisons and certain other drugs is also expected. This bill passed both Senate and Assembly last year, but was never signed by the Governor. If enacted, it would apparently operate chiefly for the benefit of the manufacturers of the required sort of bottle. The State societies introduce no bills of their own this year, and their Committees on Legislation will probably report adversely on at least 90 per cent. of the bills introduced from other sources. Without the strong support of the medical profession, it has not been easy in the past to get medical bills through the Legislature. Legislators can hardly be blamed for thinking that "when doctors disagree" it is not for them to decide. Said a man long identified with medical legislation: "A united medical profession has great influence in the Legislature of the State, and it should be the duty of medical societies to consider the practical solution of questions relating to sanitation and public health. If they can agree upon a bill that has for its ultimate object the benefit of the public, the support given by the Legislature is surprising."

PHILADELPHIA.

Officers of Obstetrical Society.—At the regular election held January 3d the following officers were elected for the ensuing year: President, Dr. John C. DaCosta; Vice-Presidents, Drs. J. M. Fisher and Geo. M. Boyd; Secretary, Dr. Frank W. Talley; Treasurer, Dr. John G. Clark.

Obituary.—Dr. R. J. Linderman, a former Bucks County practitioner, but for seven years a resident of this city, died January 6th of heart and kidney disease. Dr. Linderman served one term as State senator and held other public offices in addition to caring for an extensive practice.

Prevention of Tuberculosis.—At the January meeting of the Board of Health, committees from the County Medical Society and the Society for the Prevention of Tuberculosis urged that the following measures be adopted: (1) The registration of all cases of tuberculosis by the Board of Health; (2) the distribution of circulars of information for the prevention of the spread of the disease and for measures to check its development; (3) the sending of assistant medical inspectors to the homes or residences of all poor consumptives with instructions and supplies for fumigation and treatment of the disease; (4) the disinfection by the Board of Health of every room or dwelling at any time occupied by a consumptive; (5) the registration for record at the Board of Health of every house in which the disease has existed at any time. The matter will be held under advisement by the Board of Health until it is decided whether compulsory registration is legal under the Act of 1895.

College of Physicians.—At the meeting of January 2d, Dr. John H. Gibbon reported an interesting case of gall-stones in which symptoms of appendicitis had been present. A supposed abscess of the abdominal parietes below and internal to the right iliac crest was found to lead directly into the gall-bladder, which was unusually low in the abdomen and contained more than fifty stones. Dr. R. G. Le Conte reported the two cases of operation for cirrhosis of the liver, noted in these columns December 22d, and gave a summary of the literature on the subject. The discussion, participated in by Drs. Deaver, Meigs, and others, showed a general belief that operation in the great majority of these cases promises but little. Through the courtesy of Mrs. Joseph Leidy, Jr., an oil painting of the late Dr. Joseph Leidy was presented to the College, Dr. S. Weir Mitchell accepting the gift in behalf of the institution. The regular election of officers for the College resulted as follows: President, Dr. W. W. Keen; Vice-President, Dr. H. C. Wood; Secretary, Dr. Thomas R. Neilson; Treasurer, Dr. Richard H. Harte.

Academy of Surgery.—At the meeting of January 7th Dr. Henry R. Wharton delivered the annual oration, taking as his subject "Wounds of the Venous Sinuses of the Brain." Five cases of his own and 65 from literature were reported. Treatment is not difficult when there is an external opening. If trephining be necessary it should be done at the point of traumatism rather than according to symptoms. The most important point is careful asepsis. Gauze packing is Dr. Wharton's choice of methods in controlling hemorrhage. Sutures may be tied in bow-knots, thus making the insertion of new sutures unnecessary when the packing is removed in from three to six days. The only objection to this method is that the open wound may prove an avenue of infection. Ligation allows closure of the wound, but is dangerous in itself and is not best in ordinary cases. Dr. R. H. Harte stated that judicious suturing would do much in some cases. Where the hemorrhage is great packing must be used to control it. If the hemorrhage can be stopped by

the finger or other means, suturing will often do well. Dr. Rodman believes that packing is more reliable than ligatures or sutures as the hemorrhage should be controlled with extraordinary rapidity. The ligation of cerebral vessels is not satisfactory. Next to gauze packing forceps are the most reliable in controlling hemorrhage.

CHICAGO.

Will of Charles Higgins.—The will of the late Mr. Higgins, which has been filed for probate, stipulates that St. Luke's Hospital shall receive $10,000.

Sarcoma of the Pituitary Body.—Dr. Carl G. Swenson reported this case before the Chicago Medical Society, January 2d. Microscopic sections of the tumor of the pituitary body showed small and large round-celled sarcoma with occasional multinuclear giant-cells, and much congestion and hemorrhage.

Need for Vaccination.—There is no occasion for alarm in the fact that a few cases of smallpox have been discovered in this city and that the health authorities are taking strict measures to prevent its spread. The chief element of danger lies in the fact that recent cases have been discovered in the down-town district, and hence it is probable many people were exposed to the disease. Immediate action in the matter of vaccination is therefore the more advisable.

Free Duty on Pathological Specimens.—At a recent meeting of the Chicago Medical Society a resolution was offered and adopted that pathological speciments, which are now taxed at 20 per cent. on the cost of their production, should be admitted duty free, as they are used exclusively for scientific purposes and are of no commercial value. A copy of the resolution was ordered to be transmitted to each Senator from Illinois, and each member of Congress from this city.

Epithelioma and Healed Lupus.—Dr. David Lieberthal presented an interesting case of epithelioma which developed in the scar of lupus. Dr. Arthur Dean Bevan has seen a number of cases of epithelioma developing in lupus scars. He has likewise observed several cases of epithelioma developing in scars from burns and from lacerating injuries. He advocated surgical operations for the removal of the grossly-involved tissue and covering the surface with grafts.

Limitations of Clinical and Microscopical Evidence.—Dr. William K. Jaques read a paper on this subject. The microscope, with careful technic, at times gives results with almost mathematical accuracy which cannot always be claimed for the diagnosis dependent upon clinical symptoms alone. But in the use of the microscope the physician should keep in mind that most often the greatest safety of his patient and his own best mental development come through the close study of the clinical phenomena of disease.

Chicago Surgical Society.—At a meeting, held January 4th, Dr. L. L. McArthur showed a patient illustrating the Talma operation (operative establishment of collateral circulation) in cirrhosis of the liver. Dr. M. L. Harris reported a case upon which he performed the same operation in February, 1900, with an excellent result. Dr. Harris showed two cases of hip-joint disease treated by the Phelps method, the results being eminently satisfactory. Dr. Jacob Frank showed a man, seventy-one years of age, with an angioma of the tongue. He argued against operation in such cases, unless the growth of the tumor is rapid. Dr. John B. Murphy discussed the subject of surgery of the arteries. Dr. F. S. Coolidge mentioned some new points in tendon surgery. Dr. McArthur presented a specimen of circular adenocarcinoma of the rectum, which was removed by the Kraske operation without the disturbance of the sacrum.

GENERAL.

Plague Outbreaks.—The reports of an outbreak of the plague at Vladivostock in Russia are confirmed. There have been 19 cases, of which 15 were fatal. Four plague patients are still in the hospital and numbers are isolated.

An Antique Mosquito Remedy.—E. H. Plumacher, United States Consul at Maracaibo, has sent the following report to the State Department: "A simple remedy against mosquitoes has been employed in several places in South America and is equally well adapted to the temperate zone. It consists in planting the castor-oil plant around the house and premises." This is an old and exploded idea.

Enteric Fever and Smallpox in Galveston.—According to the report of the Marine Hospital Service there are a large number of cases of enteric fever prevalent in Galveston, Texas. One can only estimate them, for there is no ordinance that requires them to be reported to the Board of Health. Dr. William Fischer, former Health Officer, estimated the number about 450. There are 6 cases of smallpox and a considerable number of diphtheria and scarlatina.

San José Medical College.—The decision of The Philippine Commission in regard to the San José Medical College case (the point being whether that institution is owned and controlled by the United States Government or by the Church) unanimously refers the settlement of the questions involved to the courts, and provides Trustees, who, with the assistance of the Attorney-General of the Philippines, will inaugurate and prosecute the litigation. The sum of $5000 is appropriated for the expenses of the suit.

Pan-American Congress.—The Third Pan-American Medical Congress will be held February 4th to 8th inclusive. Delegates can go either by the land-routes, which are all *via* Florida, or by the water-route from New York City. Those coming from south of Washington and west of Pittsburg will probably select the Flor-

ida route, while those from the northeast will find the Ward Line more convenient. The steamer "Seguranza" of the Ward Line leaves New York January 30th, arriving in Cuba on February 3d, the day before the beginning of the Congress. The new Ward Line steamer "Morro Castle," holding 135 cabin passengers, leaves Havana on February 9th, reaching New York February 11th. The round trip is $70.00. Any one going *via* this route will be absent from New York twelve days. All information regarding transportation may be had from Dr. H. L. E. Johnson, 1402 L Street, N.W., Washington, D. C.

Any of the delegates going down by the Ward Line who desire it may, by a supplementary payment of $25.00, return *via* Santiago. This trip will take from ten to twelve days, during which time the passengers live on the ship and have their meals there if they so desire. The party goes from Havana by rail to Cienfuegos in one afternoon, there taking the steamer to Santiago and from Santiago to Nassau in the Bahamas, and from Nassau to New York. The stay in these different ports will be for a day or more. There seems to be a great deal of anxiety on the part of the delegates going to the Congress about the accommodations for themselves and the ladies of the parties. This has been most elaborately attended to by the Reception Committee, of which Dr. A. Glennan, the Health Officer of the port of Havana, is chairman. Dr. Glennan has put the Government steam launches at the disposal of the Reception Committee. This Committee is composed of English-speaking Havana physicians and an auxiliary committee of ladies. When the steamers arrive from the different countries these launches will put out with the members of the Reception Committee, male and female, and will take the delegates and their families from the steamers in the launches. *La Lucha* says: "The Reception Committee is arranging to have a ladies' auxiliary committee from Havana's best society, which will meet the guests on their arrival in order to greet with becoming dignity the ladies in the parties of the delegates." They will accompany the guests to their hotels and help them install themselves and show them every attention during their stay in Cuba. The best hotels in Havana are the Telegrafo, Mascotte, Inglaterra and Pasaje. Rates are $3.00 to $5.00 per day for board and room, American plan, the prices depending on the size and location of the room. The latest news from Cuba is that the Information Bureau will be at 105 Prado, Havana. The American headquarters will be near by.

According to present indications it is judged that there will be about 1500 delegates at the Congress. Of these probably 500 will be Cubans, 300 or 400 from the United States, 200 from Mexico, 100 from Argentine Republic and Uruguay, 50 from Brazil, 50 from Venezuela, and as many more from Colombia and other countries. There will be also quite a delegation from Chili and Peru which could not have attended the December meeting of the Congress, as it would have interfered with the Latin-American Medical Congress which was to have taken place there at that date.

Preliminary programs have been received from about half of the sections, these only represent papers that have been reported to the Secretary in this country, all the titles that have been sent to Cuba not having been sent to him as yet. The final program will not be made up until a few days before the Congress begins.

The Entertainment Committee has arranged a program which adds an attractive feature to the meeting. During the week there will be numerous excursions and entertainments for the delegates, both in Havana and the neighboring cities. A large ball will be given at the Tacon Theater. This will be under the management of a subcommittee and an auxiliary ladies' committee. The committee is sparing no pains to make the ball the great social feature of the week. On another day an excursion will be made to the sugar plantation of Mr. LaCoste in Santa Lucia, near Havana, on the Government transports. Refreshments will be served at the plantation or on the vessels. Mr. Ramon Pelayo has invited the members of the Congress to his plantation, Rosario, one of the largest in Cuba, where he will entertain them at luncheon or dinner.

Mr. Pessant will take the delegates to his establishment on the other side of the Bay and will entertain them there. The Association of Dependientes has also volunteered to entertain the delegates during their stay in Havana. There will also be an excursion to Matanzas to see the Caves of Bellamar in the Yumeri Valley.

It is requested that all delegates intending to go to Havana send their names to the Secretary, Dr. Guiteras, in order that he may determine how many will be present from this country.

Bellevue Medical Board and Dr. Moore's Dismissal.—It seems probable that the Medical Board of Bellevue Hospital will refuse to recognize the orders of Commissioner Keller, who has nominally suspended Dr. Moore on charges. There was a meeting of the Board on Tuesday last and the suspension of Dr. Moore was disapproved. When the report of the meeting was given to the Commissioner he refused to accept it.

Bellevue Appointments.—Commissioner Keller has removed Superintendent O'Rourke and appointed Dr. George Taylor Stewart to this office. Dr. Stewart was formerly connected with the Manhattan State Hospital. Since Dr. Stewart's accession a number of attendants have been dismissed for intoxication. The custom which heretofore has prevailed of employing alcoholic ward graduates will fortunately be done away with. So says Dr. Stewart.

Mills Training School.—As a result of the charges of brutality made against the pupil nurses of the Mills Training School on duty in Bellevue Hospital more than one-half the students in the school have been dismissed, have resigned or are about to leave.

CORRESPONDENCE.

ARMY MEDICAL CORPS.

To the Editor of the MEDICAL NEWS:

DEAR SIR: Your attention is called to the fact that there is at present pending in Congress certain proposed legislation that seriously disturbs the present status and efficiency of the Medical Corps of the United States Army.

The proposed law is entitled "An Act to Increase the Efficiency of the Military Establishment of the United States" (Senate Bill 4300), and in a very general way modifies the existing organization of the Army, while at the same time it provides for a damaging and offensively invidious discrimination against the Medical Corps. This fact is shown in the following particulars:

1. It decreases the percentage composition of the Corps in the grades of colonel from 3.1 per cent. to 2.4 per cent.

2. It decreases the percentage composition of the Corps in the grade of lieutenant-colonel from 5.2 per cent. to 3.7 per cent.

3. It decreases the percentage composition of the Corps in the grade of major from 26 per cent. to 18.6 per cent.

4. It increases the percentage composition of the Corps in the grade of assistant surgeon with the ranks of captain and first lieutenant from 65 per cent. to 74.7 per cent.

The significance of these proposed changes can be understood when it is remembered that, even under the existing law, it requires more than eighteen years to reach the grade of surgeon with the rank of major, while under the proposed law it will require at least twenty-five years to reach the same grade and rank. With this fact reduced to a mathematical demonstration, the inevitable result will be, first, that the more worthy young men will not apply for commission, and, secondly, that the relatively less worthy men who do enter the service, discouraged by the certain impossibility of reasonably prompt promotion, will resign, leaving their places to be filled by untrained and consequently less efficient men. The ultimate disaster from this contemplated change, however, will consist not alone in a lowered status of the medical service but in (1) increased disease and death-rate among the men, (2) a diminished and otherwise weakened force on the firing line, and (3) a material augmentation of the pension-roll.

In view of the foregoing facts and in view of the fact that every other corps of the Army is better graded than is the medical, every member of the medical profession is hereby earnestly solicited to send at once to his United States Senator and Congressman an urgent and emphatic protest against the proposed provisions in Senate Bill 4300 relative to the Medical Corps of the United States Army.

CHARLES A. L. REED, M.D.,
President of the American Medical Association.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, December 29, 1900.

THE EPIDEMIC OF ARSENICAL POISONING FROM BEER-DRINKING—REPORT OF THE MEDICAL OFFICER OF HEALTH FOR MANCHESTER—NUMBER OF DEATHS FROM PERIPHERAL NEURITIS DOUBLED IN MANCHESTER—INFANTS POISONED BY THEIR MOTHERS' MILK—THE DIFFERENCES BETWEEN THE STAFF AND BOARD OF THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC—FAILURE OF THE PROPOSED INQUIRY—AN "IMPERIAL PHARMACOPŒIA"—THE USE OF BORIC ACID AS A FOOD PRESERVATIVE UPHELD.

DR. NIVEN, Medical Officer of Health of Manchester, has issued a very important report on the "epidemic" of peripheral neuritis due to drinking arsenical beer. Directly on ascertaining that arsenic had been discovered in a sample of beer, he improvised a laboratory and examined the brewing sugars used in the twenty Manchester breweries and the glucose used in the manufacture of jams and cheap sweets. In forty-six specimens of glucose from the breweries arsenic was found only in that emanating from one firm which contained it in considerable amount. Five of the twenty breweries were using this material. The glucose used in manufacturing the sweets was free from arsenic. It appears that about 2000 cases of arsenical poisoning from beer-drinking have come under observation in Manchester. No doubt in addition to these there must have been a large number of milder cases which were never seen. No cases have yet been authoritatively described in which death was due to arsenical poisoning, but the mortality statistics give important information. The deaths from peripheral neuritis have nearly doubled in 1900. Moreover, the difference is confined to recent months, for up to the May there were only five deaths from this cause. Taking the first 48 weeks in the years 1897, 1898, 1899, and 1900, the deaths from peripheral neuritis in Manchester were 11, 17, 18, and 39, respectively. Again, taking together the deaths from the following diseases (in which arsenical poisoning may have played some part) *viz.*, peripheral neuritis, neuritis (other), alcoholism, and cirrhosis of the liver, the figures for these periods are 172, 141, 188, and 253, respectively. In my last letter I briefly described the principal symptoms observed in this remarkable epidemic. The following statistics of 54 observers supplement what I have said. Only 6 recorded the absence of eruptions. Tenderness of the calf on pressure was absent in only 5 observers' experience. Pain, swelling and tenderness of the feet were observed by 34. Paralysis or paresis was noted by 48. Many remarked on the great increase in the number of cases of herpes zoster. Pigmentation of the skin varied from golden yellow patches on the face, chest and feet, to more extensive bronzing and a deep mulatto pigmentation covering the front of the chest and recalling Addison's disease. Edema was of frequent occurrence. Several practitioners drew attention to loss of memory and delusions. Persons of all ages and both sexes suffered. Dr.

Kelynack, Assistant to the Professor of Medicine, Owen's College, Manchester, has described a very interesting case in which an infant at the breast was poisoned by its mother's milk. A woman, aged thirty-two years, drank stout after her confinement. At the end of five weeks she experienced "numbness" of the fingers, "jumping" in the feet, "running and smarting" in the eyes, and became hoarse. At the same time the child began to vomit whenever it suckled. The mother had tearful eyes, marked erythema and keratosis of the feet, and sensory symptoms in the distal parts of the limbs. Walking was very painful. There had never been nausea, vomiting, or diarrhea, and the secretion of milk was plentiful. The infant was puny and much wasted and it snuffled. Its feet were slightly erythematous. The mother was directed to cease taking stout, to stop nursing and give the baby cow's milk and barley-water. Both improved at once and the baby ceased vomiting. An analysis of the mother's milk failed to disclose the presence of arsenic. The clinical features, however, are sufficient to warrant the diagnosis of arsenical poisoning of the infant from the milk. A similar case was observed in another infant whose mother was recovering from arsenical neuritis. The baby had furred tongue, gastro-intestinal catarrh, vomiting and diarrhea. A few days after weaning it was quite well. A case of arsenical poisoning occurred in a little girl of two, the daughter of a publican. She was petted by the customers who were in the habit of giving her "sups" of beer.

The differences between the medical staff and the Board of the National Hospital for the Paralyzed and Epileptic are, I regret to say, no nearer a settlement. At the request of the Lord Chancellor, who is a member of the Board, an eminent lawyer, the Right Honorable Sir Ford North, consented to conduct an inquiry into the allegations of the staff concerning the care, comfort and treatment of the patients. The medical staff has very properly refused to recognize the proposed inquiry for three reasons: First, the tribunal has been constituted by only one of the parties to the difference; second, the scope of its action is limited to domestic condition of the hospital and excludes the subjects of its constitution and management; third, although dealing with questions purely medical, such as the diet, care, treatment and the nursing of patients, it was to be conducted without medical assessors. The staff also complains that, although the resolution of the Board with regard to the proposed inquiry was passed on November 2d, it was not communicated to them until December 6th, when, although they were invited to appear by counsel, it had only four days in which to instruct counsel for the purpose. As I have already informed you, the staff previously refused to take part in any inquiry of a restricted character which did not include the points of difference to which they themselves attached supreme importance. The consequence is that the proposed inquiry has had to be abandoned. Thus this valuable institution is torn by a controversy which must seriously impair its efficiency, if not destroy it altogether.

An additional link between the several portions of the British Empire has just been forged by the General Medical Council. At one time a Pharmacopœia was issued by each of the Colleges of Physicians of London, Dublin, and Edinburgh, each of which was the legal authority for the corresponding divisions of the United Kingdom. Naturally this caused much inconvenience, for the preparations varied in strength in the different countries and an English druggist was much inconvenienced by the occasional prescription of a Scottish preparation or *vice versa*. Hence, the issue by the General Medical Council of a general Pharmacopœia applicable to the whole of Great Britain was hailed as a great convenience. This "British Pharmacopœia" was prepared by a committee containing members from each division of the United Kingdom and incorporated what was best in the local Pharmacopœias. It received the sanction of an Act of Parliament and every druggist was bound under penalties to sell only what was in accordance with its standards of strength and purity. About every ten years it has been the custom of the Council to issue a new Pharmacopœia so as to include all new preparations of sufficient importance and reject others which have fallen into desuetude. Now, many medicinal plants and other substances considered to be valuable are in constant use in India and the colonies and comparatively unknown in England. It has been decided that those of sufficient importance should be brought under official recognition so as to insure a proper and uniform standard of activity. The result will be to supersede the British Pharmacopœia by an "Imperial Pharmacopœia" embracing the pharmacy of the whole Empire. As a first step in this direction the committee has been engaged, with the assistance of the Indian and Colonial Governments, in procuring from all parts of the Empire the necessary information from medical practitioners, scientific societies, and all other bodies and persons likely to be in a position to afford it. The first result has been the publication of an "Indian and Colonial Addendum" to the British Pharmacopœia, containing the necessary details with regard to plants or substances which in the country yielding them may be employed as substitutes for those in the British Pharmacopœia. Thus in India there are several kinds of bland, native vegetable oils which may be used in place of olive oil and there are native plants which may be used to replace others which would be rendered unduly costly by importation. Moreover, an official character is now given to medicines which have been used from time immemorial by the natives and which possess qualities which have stood the test of scientific investigation. The addendum will be subjected to the criticism of the medical authorities in the localities in which it chiefly applies, and will eventually in some amended form be incorporated with the original work. The attention thus devoted to Indian and Colonial plants cannot fail to further the advance of therapeutics in general.

The question whether boric acid is injurious when used as food preservative has been of late

the subject of much discussion and litigation. Among authorities considerable divergence of opinion prevails. A case of considerable importance which allows the use of boric acid has just been decided. A provision dealer was summoned by a food inspector because his butter contained 0.8 per cent. of boracic acid. The medical officer of health for the county of Wilts, in which the case occurred, gave very strong evidence for the prosecution. He said that boric acid was an unnecessary and dangerous addition to food and caused infantile diarrhea and occasionally death. In cross-examination, however, he failed to give any instances. The medical officer of health for Southampton then testified to the entire harmlessness of the preservative in the quantities found in this case and to its great value and increased use in medicine; but he drew a sharp distinction between its use in milk which is consumed in considerable quantities by children and invalids and its use in butter, of which no one would eat enough to experience any effects from the acid. A provision merchant gave evidence as to the necessity of a preservative of this class and gave figures to show the great falling off in the sale of old-fashioned salt butter since preserved butter was introduced.

UTERINE INFECTION—MYXEDEMA AND THYROID EXTRACT—ABNORMAL LENGTH OF THE SIGMOID FLEXURE—SYPHILITIC HYDROCEPHALUS—HEMORRHAGE FROM THE CEREBRAL SINUSES—FIXATION OF THE SCAPULA TO THE RIBS AFTER EMPYEMA—THE O'CONNOR ELEVATOR IN SHORTENING OF THE LOWER EXTREMITY—GELATIN AND ANEURISM—RUPTURE OF THE SMALL INTESTINE—ACQUIRED DEXTROCARDIA—RECTAL EXPLORATION AND ITS RELATION TO INCISIONS FOR APPENDICULAR ABSCESS—NEW FORM HEMOGLOBINURIA—RARE SITES OF PRIMARY SYPHILITIC LESIONS.

Schaeffer, at the Berliner med. Gesellschaft, November 7, 1900, discussed infections proceeding outward from the uterus, which was the subject of C. Abel's paper at the preceding meeting. His points were in brief that iodoform gauze is an excellent means of dilatation; vaporization is of little value because the experiments of Flatau show that the temperature at which the steam reaches the uterus is too low to be of value; lysol douches are equally of little efficacy; extirpation applies well in selected cases but its indications are not yet fully determined; cold packs for the reduction of temperature are very useful and comforting as they are usually followed by heavy perspiration.

Gottschalk said that true septic and merely sapremic endometritis must be differentiated. The latter yields at once to clearing out of the contents of the womb. Intra-uterine irrigations of a one-per-cent. solution of soda are more satisfactory than lysol douches. Dilatation with instruments causes hyperemia which is to be avoided. Local use of alcohol fails just as do other disinfecting means. Removal of the womb has not been satisfactory in his practice. The most important two things are sustenance with good food and proper stimulation preferably with some form of alcohol. Sodium salicylate on account of its causing leucocytosis is valuable and quinine did wonderful service in one case of pyemia. Most of the so-called septic abortions are only sapremias pure and simple.

H. Neumann said that as in myxedema in the adult so in sporadic cretinism with or without idiocy thyroid extract works wonders. There occur decrease of the unhealthy fat body, increase in growth, rapid development of the teeth and improvement in the bodily functions. Absolute cure he has never seen, but the earlier the treatment is begun the more rapid and satisfactory are the results. Such cures may often be lost by the fact that the disease is often confused with rachitis, which is really often associated with it. The disease really occurs rather frequently.

Stolzner, at the meeting of November 14th, said that in the last two and one half years at the Heubner Polyclinic he had treated five cases of infantile myxedema with favorable outcome. One was apparently completely cured. The others were much improved but it was a question how far the mental development would continue. Too much emphasis cannot be laid on a distinction between cretinism and rachitis.

Ewald reported three cases in the polyclinic of of the Augusta Hospital and presented one. As in the treatment of adults so of children the thyroid extract must be continuously given and in ever increasing dose. He has one adult who is now taking very large doses. The system appears to become accustomed to the medication but unfortunately not to its occasional deleterious effects. To counteract such he now uses arsenic.

Detert, at the Verein für innere Medicin in Berlin, November 5, 1900, reported the case of a two-and-one-half-year-old child with obstinate occlusion and partial displacement of the sigmoid colon. The treatment was by high intestinal injections. After the sound had passed a certain distance up it encountered an obstruction diagnosed as the lower end of the upper segment of the bowel, situate about thirty centimeters proximal to the anus. When the sound passed this considerable flatus was voided. The prognosis appeared uncertain though the treatment would be continued.

Neumann stated that in literature there is only one full cure of hydrocephalus mentioned—Heller. This was probably syphilitic like his own case reported. Three weeks before coming under his care the three-year-old baby had begun to show distinct signs of hydrocephalus, spreading of the fontanelles and sutures, typical hydrocephalic appearance, depression of the mental faculties, wrinkling of the skin, and enlargement of both the liver and spleen. Iodide of potash 0.25 gms. daily to a total of 75.0 gms. (4-1100 grains) cured rapidly and very fully. Even an early affection of the eyes (clouding of the retina, obscuring of the papilla and scattered spots) also disappeared.

Bertelsmann, at the Aerztlicher Verein in

Hamburg, November 13, 1900, brought forward a woman cured of intracranial hemorrhage from the sinuses. She had been knocked down by wagon and fell against a sharp stone upon the occiput. At first she was unconscious and later mentally clear. This was followed by delayed signs of cerebral damage. These were: Stupor, pupillary inequalities, numerous epileptiform seizures, vomiting, slow irregular pulse. Operation was at once determined upon because edema of the lungs was imminent and although the interval of consciousness made it difficult to be certain of the site of the damage, secondary hemorrhage was the final diagnosis. There were no signs of bleeding from the middle meningeal artery, therefore it was decided to explore the site of external injury. Here a fissure was found crossing the sagittal suture at an acute angle. Upon removing a large bone-flap, free evacuation of blood occurred followed by better pulse-conditions. Exploration of the lower corner of the wound caused violent flow of blood indicating wound of a sinus, which had to be packed at once. Noteworthy in the after-course of the case are the following facts: A two-day active jactitation and stupor followed with also a slight attack of spasm accompanying; on the twelfth day after the operation consciousness complete for the first time; absence of patellar reflex from the fifth to the ninth day; removal with no bleeding of the tamponnade on the twenty-first day; slight recurrence of stupor directly thereafter with acute moderate dilatation of the heart and various slight cerebral excitement of very temporary duration, and evanescent right ocular rectus internus paresis with double vision. At the present time the patient is in good condition, free from either psychic or somatic lesions and able to earn her own living.

SICK introduced before the meeting a patient who had been under treatment for one year for tuberculous empyema which had a history of three years' standing. The ribs had been resected and various thoracoplastic procedures followed until cure resulted. As an after-effect there had occurred ankylosis between the ribs and the scapula which caused loss of function of the arm. In order to restore this the lower half of the scapula had to be resected. The use of the arm had returned to the degree of permitting him to earn his living, although there was considerable deformity.

WIETING had a patient with one lower extremity twenty centimeters shorter than its fellow, for which he had successfully applied the O'Connor elevator, designed essentially to improve the cosmetics of the case by doing away with the heavy clumsy thick sole and make the foot of the affected resemble that of the normal side. The body-weight is not received on the horizontally placed but a strongly oblique sole, so that the foot is brought somewhat into the equine position, but without making the patient walk on his toes. Through obliquely placed blocks the sole of the foot really takes the weight upon the slanting base of the boot. The apparatus really consists of two boots, outer of the usual appearance, and inner consisting of this aluminium splint with leather shoe-like covering to fasten the foot to it. The whole device weighs about four pounds.

RUMPF took up the subject of injections of gelatin in the treatment of aneurism with particular reference to the experiments of M. Schmidt and the recommendations of Lancereau to use a two-per-cent. solution and one hundred cubic centimeters at a time. He had had his patient under observation for one and one-half years, an aged inmate of a hospital and retreat. In January, 1900, there developed a tender place over the third rib which slowly became an erosion through an aneurismal sac with all the signs of pulsation, etc., until finally a hen's-egg sized tumor was present. The injection above described was resorted to with the result that in a short time another was necessary. After that the tumor disappeared and apparently cure was brought about. After this persisted a few months slow relapse appeared till now the conditions were just what they had been in January. The treatment was to be repeated and the results of it would be shown to the society at a later period.

RINGEL reported a case of rupture of the small intestine in a gardener with very marked kyphosis. He fell from a tree upon his abdomen and showed, on admission to the hospital, small thready pulse, fever, dulness in the flanks and signs of beginning peritonitis. Immediate laparotomy was done. The jejunum was found ruptured high-up for three inches and sewn. The abdominal cavity was filled with intestinal contents and the peritoneum was slightly involved. Its toilette was carefully attended to and the parieties were closed *without drain*. An almost fever-free course followed, interrupted only by a small mural abscess.

LOHSSE, at the Med. Gesellschaft zu Madgeburg, October 11, 1900, described the clinical picture of a case of dextrocardia acquired through collapse of the right lung, through phthisis of that side progressing since 1893, at which time the heart was still situated in its normal position. The following are the details: Absence of heart dulness and in the skiagram of the heart-shadow on the left side; pronounced emphysema of the left lung carrying its right limits over to the right margin of the sternum; great enlargement of the left chest; pulsation in the fourth interspace near the anterior axillary line and in the fifth interspace near the parasternal line; cardiac dulness beginning at the lower border of the fourth rib near the anterior axillary line, following this rib inward and in the parasternal lining turning down toward the midline; heart sounds at their acme over this same area; infiltration of the upper part and cirrhosis of the lower part of the right lung; great pleural thickening evidenced by marked dulness and feebleness of breath and voice sound; sinking-in of the right chest until five centimeters smaller than the left; no subjective circulatory symptoms; right radial pulse the stronger; tubercle bacilli in the sputum. This dextrocardia is almost certainly acquired, because seven years ago when his lung trouble began, so far as can

be ascertained, the heart was in its correct site. Moreover, through the past year the cirrhosis of the right lung has influenced it. The present position of the heart was only partially indicated by the radiograph, and was still further to be examined and established on cadavers by Garmer and Bard, who found the heart as a whole may be pushed to the right, the base and apex maintaining a normal relation. Still further in evidence is the fact that the attachment of the pericardium to the diaphragm is such that experimentally the heart can not be twisted on its base so as to displace the apex to the right. Again the physical signs in this case disprove this because the base was evidently up and to the right, while the apex remained down and to the left, each with widely separated and distinct pulsation corresponding to the length of the heart. The difference in the radial pulses probably bespoke a kinking in the branches of the aorta. In literature such cases are rare, but none is of so large a degree of displacement.

Langemak, at the Rostocker Aerzteverein, September 8, 1900, brought out the point that there is still too little unanimity between the internes and the surgeons in the treatment of appendicitis and that more and more surgeons are joining the school of immediate operators. But in one point there is no difference of opinion, namely, that palpable purulent exudates about the appendix always deserve surgical treatment. The widely different positions of the appendix and hence of the exudate must determine to a degree the avenues of approach. For years it has been known that the relation of the appendix to the true pelvis renders its symptoms often like those of disease of the adnexa and hence the vagina is a convenient route for evacuating abscesses so situated. In males and in female infants such abscesses will be near the rectum. In the clinic at Rostock, Professor Garré has operated on a number of patients in this way and the speaker praised this avenue as easy and direct in selected cases. Hence is recommended exploration of the rectum in all cases of appendicitis with a view to following that as a route to the abscess.

L. Michaelis stated the following history: A woman had had a ruptured tubal pregnancy, resulting in a small retro-uterine hematocele and blood free in the abdominal cavity, then collapse. The hemoglobin was at this time twenty-five per cent. and the blood contained single small kernel-like bodies. Saline infusion was resorted to, followed by improvement in a few days. Four weeks later the hemoglobin was seventy per cent. On the day after admission the urine was blood-red, with a few granular casts, a little albumin, some blood pigment but no blood cells. The next day the albumin and hemoglobin disappeared from the urine. On the twenty-fifth day sudden rise of temperature to 38.6 C. with chilliness and renewed attack of the hemoglobinuria even more severe than the former. Three days later normal urine again and after eighteen days of further observation was still normal. This interesting case the speaker sought to explain with the help of Bordet's hemolysine of the hypothesis of Ehrlich-Morgenroth and held that it should be regarded as the first example of autolysine action.

Stadelmann in the discussion said that for the production of hemoglobinuria some blood-poison is necessary, as exemplified by pyemia. If the theory of Michaelis were correct, this condition would be oftener encountered.

Hahn, at the Aerztlicher Verein in Hamburg, October 30, 1900, reported a child three years old with a primary syphilitic sore on the upper eye-lid. The submandibular glands were affected and a macular secondary exanthem established the diagnosis. In the same family, a second child had the initial lesion on the tip of the nose and a third on the wing of the nose. An adult in the household with florid secondary lesions was the source of all these infections.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held October 19, 1900.

A. B. Judson, M.D., Chairman.

Diagnosis of Pott's Disease.—Dr. H. Gibney read this paper, which was illustrated by the exhibition of photographs and the presentation of patients.

Case I. Cervical Pott's Disease.—Girl eight years of age. Marked deformity from disease of long duration of several of the cervical vertebræ with scars of abscesses below the site of the disease. Treatment had been discontinued in the summer of 1900. The child had worn a head support combined at first with a plaster-of-Paris jacket, and afterward with Knight's spinal brace. Pain near the seat of the disease, which is often absent in the other regions, is a common symptom in this region, with a sensitive area at the side of the neck, severe pain with voluntary motion of the head and neck and apparent torticollis yielding easily to traction applied in such a manner as to hold the head in its normal position. Before treatment, relief was sought by a supporting hand held under the chin. Abscesses are not an uncommon incident of cervical disease, detected by an examination of the posterior wall of the pharynx or burrowing under the superficial muscles of the neck.

Case II. Cervical and Dorsal.—Boy five years of age, affected for two and a half years with disease extending from the middle cervical to the middle dorsal region. Two abscesses had opened spontaneously at the sides of the neck under the sternocleidomastoid muscle. He had worn a plaster-of-Paris jacket and a jury mast for eighteen months. A grunting noise with each expiration is almost characteristic of caries of the dorsal region and an early diagnosis is greatly assisted by the occurrence of gastralgia, the appearance of a

careful gait and a peculiar, apprehensive attitude, expressive of timidity and insecurity, and an instinctive desire to avoid disturbance of the diseased vertebræ. The first sign of a kyphos is seen in a slight angle breaking the long natural curve of the spinous processes observed in profile as the patient lies prone.

Case III. Tenth Dorsal. First Stage.—Girl eight years of age. Under observation since May 5, 1900, and regarded for a time as a case of lateral curvature with a hypersensitive, almost neuralgic, condition of the spine. Very recently a suspicious point had been detected at the tenth dorsal and treatment would now be by Knight's support.

Dr. T. H. Myers said that lateral curvature often attended incipient Pott's disease and obscured the nature of the more serious affection, as had occurred in the present instance. He thought that these doubtful cases should be considered as caries of the vertebræ until a positive diagnosis could be made.

Dr. H. S. Stokes said that in obscure cases of early Pott's disease the plaster-of-Paris jacket was valuable as a means of verifying the diagnosis. In cases in which there was at first no apparent deformity, if the jacket were applied and left on for a time, then removed, the kyphosis, if present, would be seen at once. This effect was seen too soon to be due to further progress of the disease, nor could it be said that the jacket had caused the kyphosis. In a doubtful case, showing no deformity, he would apply the jacket as a diagnostic measure.

Dr. A. B. Judson said that similarly the tumor of white swelling of the knee became more obvious soon after the beginning of mechanical treatment, probably from pressure and restraint applied to the soft parts.

Dr. Gibney resumed his presentation of patients as follows:

Case IV. Dorsolumbar.—Girl, two and one-half years old, affected with disease of the dorsolumbar region of nine months' duration. No abscesses. The spine had the marked rigidity which attended disease in this region and marked gastralgia had been a part of the history of the case. A plaster-of-Paris jacket had been applied at first, but lately a recession of the deformity had been observed to follow the strict application of a Bradford frame.

Case V. Eleventh Dorsal. Third Lumbar.—Girl thirteen years old, who had recently come from Russia with a very marked kyphos. But little had been learned of the history and treatment. Sinuses were discharging at points where abscesses had opened spontaneously. The gait and attitude were very characteristic of disease in this region. A Knight support had been applied and as the child's general condition was fair, the prognosis was good.

Dr. Myers said that the characteristic attitudes of Pott's disease, although early and important signs, were also seen in osteitis of a syphilitic or malignant origin. It was, therefore, important to consider the personal and family history, the age, the location of the disease and the mode of onset as well as the pain and tenderness. The fourth patient presented had been free from pain in the abdomen and legs. Pain in the terminations of the nerves was not so early or so prominent a symptom in the lumbar as in the dorsal region, while local tenderness was more apt to be recognized in the cervical than in the other spinal regions. In the cervical region the vertebral articulations might become infected by organisms gaining access from the pharynx after measles or scarlet fever with resulting muscular spasms and malpositions of the head simulating those of Pott's disease and it might be a long time before it could be decided that a postpharyngeal abscess had its origin in vertebral caries. A long time might also elapse before it could be known that a traumatic osteitis in the cervical or lumbar region had become tuberculosis. There were absolutely no pathognomonic symptoms.

Dr. J. P. Fiske said that he had not as yet seen a case of traumatic spine go on to tuberculous caries.

Dr. Judson said that Pott's disease presented some unexpected features, such as the occurrence of pain in the front of the trunk while the disease was in the back. Some patients also with serious and purulent destruction of bone maintained the appearance of robust health. This affection, justly compared with fracture of a central and most important part of the skeleton, was as a rule so free from local pain and disability that when these symptoms were persistent and exaggerated Pott's disease gave way to malignant disease of the vertebræ as a probable diagnosis.

Dr. Myers said that the diagnosis of the latter affection would be assisted by consulting the following clinical features: Rapid emaciation and loss of strength, every motion exquisitely painful, pain constant but motor paralysis less constant, marked muscular rigidity, kyphosis absent or late in its appearance, occurrence at any age.

Dr. Fiske said that as they all had deformity the presentation of these patients failed to throw light on the most important question, that of making an early diagnosis. Diagnosis before deformity was an extremely difficult thing, and proportionately important and desirable. Suspicious spinal symptoms might be produced by rheumatism, by neurotic reflexes, myositis following a blow or by some other and more obscure muscular lesion. He had seen cases in which circumcision had dissipated spinal symptoms which had been hard to interpret. Muscular spasm or spinal rigidity could not alone support a diagnosis of tuberculosis of the spine.

Dr. C. R. L. Putnam recalled the history of a case which he had observed in a foreign hospital. A man, fory-five years of age, totally paraplegic, was thought to have disease of the first and second lumbar vertebræ with a tuberculous abscess pressing on the spinal cord. The removal of two laminæ revealed the presence of an echinococcus cyst behind the theca. The result was unfavorable.

Dr. Myers had seen a tumor of the lower cervical cord produce, not only symptoms of pressure on the cord, but also the local pain and muscular rigidity which usually attend vertebral disease.

Dr. F. A. Goodwin of Susquehanna, Pa., said that railway brakemen, from their custom of jumping off and on trains in motion, frequently received spinal injuries accompanied by rigidity, pain on pressure and other symptoms of true Pott's disease. Perfect rest for a long time, however, almost always cleared up the diagnosis. It had been his misfortune to see a number of patients in whom the diagnosis of Pott's disease had been inexcusably postponed by eminent authorities. He instanced the history of a little boy who had been treated for asthma and other affections without an examination for kyphosis which had existed to a marked degree for a long time during which grunting expiration, pain, inability to stoop and rigidity of the spine had been obvious features of the case. On the other hand, he had made a diagnosis of Pott's disease in a little girl who had a board-like rigidity of the spine. She could not stoop to pick up a coin from the floor without putting a hand on the knee for support. Her recovery without treatment was explicable by the supposition that there had been synovitis of the costovertebral and costotransverse articulations. He thought that a diagnosis before the appearance of deformity was exceptional and recognized the inherent difficulties of the situation.

Dr. L. W. Ely referred to the opinion which prevailed among general practitioners that Pott's disease in the dorsal and lumbar regions was attended by sensitiveness to pressure on the spinous processes. Although this supposition was not unreasonable, in view of the nature of the lesion, the fact was that this symptom was of very rare occurrence. Running the fingers down the spinous processes in a doubtful case was of almost no value in making a diagnosis.

Dr. G. R. Elliott said that in a rapid carious process we had the full quota of symptoms clearly defined while a slow morbid action gave but few and obscure indications. The X-ray had been a disappointment in this field. It had failed to reveal a deposit before the appearance of deformity. What was desired was an early diagnosis, a diagnosis before deformity which, of itself, made the diagnosis without the assistance of symptoms or any other signs. A most important early symptom was abdominal pain. How often are we told of the postponement of a spinal examination in favor of treatment for intestinal disturbance until an early diagnosis was impossible. A child should be examined with all the clothing removed. In no other way could the obscure signs be recognized. The enlarged abdomen was another important early sign. The contraction of a psoas muscle, exposing one to the risk of a faulty diagnosis of hip disease, might be the earliest sign of Pott's disease. He recalled the case of a child who was said to have cervical caries of two months' duration following scarlet fever with rheumatism. There was painful spasm of the muscles of the neck, the head resting on the shoulder and a hand supporting the chin. The symptoms all disappeared without fixation after treatment by simple suspension. On the other hand, a patient with supposed rheumatism of the spine, whose symptoms included pain in the back, stiffness and misunderstood reflex spasm, was bathed, rubbed and shaken up for three months and, after vigorous antirheumatic treatment had lasted for a year, the appearance of kyphosis determined the diagnosis.

Equilibrium disturbed by kyphosis of Pott's disease and restored by lordosis.

Dr. Gibney said that photographs clearly presented the attitudes, but failed to display the characteristic movements and deportment of the patient affected with Pott's disease. There was in his collection, however, one which graphically copied (see Fig. 1) the overerect attitude which was assumed by the patient's entire figure and threw light on the mechanism of the production of the lordosis which appeared as a compensating curve below the kyphos.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 6, 1900.

The President, William H. Thomson, M. D., in the Chair.

The anniversary discourse was delivered by Dr. Robert Abbé, the subject being "The Problem of Appendicitis from the Medical and Surgical Side."

Changes in Surgical Interest.—The subject of most interest to surgeons at the present moment is appendicitis. As an ordinary surgeon in a reasonably busy practice may have 100 operations a year for appendicitis, this interest is evidently jus-

tified by the conditions. Other subjects of surgical interest come and go, but this continues because of its pathological significance. Twenty-five years ago the questions of interest to the surgeon were very different from those which occupy him now. One of the most important subjects at that time was operation for strangulated hernia. This has lost a great deal of its importance because operations for the radical cure of hernia have greatly lessened the number of strangulations which take place. Another important subject at that time for the surgeon was pyemic conditions of joints. These came as the result of infection, and in this day when asepsis is the rule such cases are very rare. Kidney abscess was another subject of interest a quarter of a century ago that has lost most of its importance at the present time, because vesical infections are now treated more carefully and more rationally and ascending infections of the kidney do not take place. The surgery even of tuberculous bone affections has diminished in importance, because of the better sanitary surroundings of the population most liable to these conditions. There is no doubt that no profession is doing so much to end its own usefulness as the medical one.

Phases of Appendicitis.—Appendicitis constantly presents new problems. It is not a new disease. Some twenty-five years ago, when the word pneumonia first came into vogue to represent a disease distinctive from a number of pulmonary conditions that had formerly been grouped together, a similar state of affairs occurred with regard to this disease. There seemed to be many more deaths from pneumonia than formerly and apparently the disease was epidemic. Just as many deaths occurred from appendicitis before the invention of its name as since. Two diseases particularly received the credit for the fatal affections which are now known to have been due to appendicitis; these were inflamation of the bowels and peritonitis. Inflammation of the bowels formerly occupied a prominent place in hospital mortality statistics. Now it has disappeared.

Specimens of Appendices.—Dr. Abbé then said that he had not intended to review the statistics of appendicitis, nor to suggest any modification of present operative methods, nor had he any pet theory to air in the matter, nor did he even wish to dogmatize on the subject. The main object of his paper was the discussion of a set of specimens of diseased appendices which had been removed, carefully preserved in alcohol, and then studied. In order to preserve these specimens as far as possible in the state in which they were when removed, they were first injected with alcohol and then placed in a vessel containing alcohol. After hardening they were split in order to show the character of the interior of the appendix and especially to exhibit the kind and number of strictures that existed in the different cases. Nearly always behind the strictures were found pockets of infected material, sometimes only mucopurulent in character, but sometimes composed of pure pus. Many of these cases were associated with symptoms of chronic dyspepsia, which show the reflex affect on the gastro-intestinal tract of the presence of the pus as well as the effect of infective material in the absorbents of the digestive system.

Concretions.—In many cases concretions were found behind the strictures. Whenever concretions were found they always occurred on the distal side of the narrowing of the lumen of the appendix. These concretions very rarely contain food particles, nor are they formed around some foreign body as a nucleus, although this has often been said to be their usual mode of origin. The concretions are composed of desquamated epithelium from the mucous membrane of the inflamed appendix and of bacteria. Their formation shows that the pathological condition in the appendix has existed for a long time. It is an entirely false idea to think that these concretions are formed in the cecum and are dropped from there into the appendix. It is only when the stricture of the appendix is so tight that the desquamated epithelium finds no mode of egress that the concretions form.

Foreign Bodies.—Foreign bodies are found very rarely in the appendix. Some of the specimens presented show very clearly the appearances that led to the theory that the seeds of certain fruits sometimes find their way into the appendix and became the source of appendicitis. The concretions often imitate such seeds in their form and so are mistaken for them on casual observation. Only rarely is a kinking of the appendix the cause of appendicitis.

Etiology of Appendiceal Strictures.—Strictures of the appendix are due to two causes, ulcers and severe catarrhal inflammation. Experience with strictures in other parts of the digestive canal, especially the esophagus and the rectum, makes it clear that such strictures take many years to develop sufficient contractility to narrow the lumen. There is no doubt that the beginning of a stricture in the appendix may go back twenty-five years.

Undoubtedly a severe intestinal disease in children, such as infantile colitis, is a prominent and frequent cause of ulcerous conditions which invade the appendix and leave a tendency to the formation of connective tissue which later becomes a stricture. Influenza when it attacks the intestinal canal is probably also a not infrequent cause. The first recognized attack of appendicitis is really only a terminal stage of an affection which has existed for many years.

Development of Appendicitis.—When a stricture exists in the appendix any disturbance of the circulation of the intestine may easily lead to a swelling of the mucous membrane with occlusion of the canal. If the bacteria behind the stricture are of virulent character, this occlusion may soon become permanent by inflammatory adhesions and, then, as there is no free exit for the infective material, a virulent abscess results. Sometimes the rapid growth of bacteria within the shut-up appendix and the consequent manufacture of purulent material increases the pressure within the

appendiceal pouch and forces open once more the occluded lumen of the appendix.

These are the cases which improve under medical treatment and seem to get better. Occasionally Nature provides an exit for the pus by making an accessory opening through some part of the intestinal canal. This constitutes Nature's method of curing the disease. The cure is rare, however, and is usually imperfect. The ordinary cures under medical treatment are in no sense radical. Recurrences of the appendicitis can be looked for at any time and the stricture of the appendix, of course, continues to exist.

Multiple Appendiceal Strictures.—As many as seven or eight strictures of the appendix, all of them fairly tight, have been found in one appendix. These usually represent successive attacks of appendicitis, occurring at rather long intervals. The appendiceal inflammation leads to the formation of connective tissue and as this is contractile in character, strictures result. Very often when the history of the case is carefully traced and the condition of the appendix, the number of its strictures and their character, carefully studied, the two sources of information will be found to complete and explain one another. The appendiceal history is written in the tissues of the appendix itself.

Special Cases.—One of the appendices removed by Dr. Abbé and presented among the specimens was markedly gangrenous. It came from a case in which the patient had had a preceding mild, but typical, attack of appendicitis twenty-five years before the one in which the acute symptoms required the removal of the appendix. The stricture which had formed in this case had behind it a concretion and it was this, doubtless, that helped to the acute exacerbation which ended in gangrene. The concretion in an appendix may act as a ball-valve, sometimes preventing the exit of material within the appendix and sometimes permitting it. This gives rise to slight symptoms of appendicitis. The perforaton of the appendix not infrequently occurs where the concretion is pressing upon the walls of the appendix. Pressure leads to thinning of the walls and finally to complete perforation.

Appendicitis and Gout.—It has been said that appendicitis occurs especially in gouty subjects or, at least, that in certain cases the appendicitis seems to be of gouty origin. This explanation of the etiology of the disease is apparently due to the fact that in certain cases joint symptoms have been noted in connection with recurring appendicitis. It is probable in most of these cases, however, that the reason for the joint symptoms is really a mild form of pyemia induced by the constant presence of the septic focus in the diseased appendix. Mechanical factors are now held to be the principal etiological elements.

Latent Appendicitis.—Certain cases of appendicitis run a most insidious course. That is, the disease exists for a long time, yet gives no symptoms that call attention to its presence. It seems better to call such cases latent, rather than chronic appendicitis. When stricture exists it is not hard to explain such cases. A bicycle ride may cause intestinal congestion; or the intestinal disturbance incident to the irritaton of some unsuitable food, green apples, or the like, may produce the same effect. Menstrual disturbances are also factors in the production of a congestion which causes appendicitis. Each attack that occurs makes the stricture tighter. Relief afforded by any means other than a radical surgical operation is only a lull in the general pathological process which is usually progressive.

Anomalous Cases.—At times there is found within the lumen of an appendix after operation an accumulation of sterile yellow debris. At times, too, the virulence of the infective material within the appendix proves to be not so fatal as might be anticipated from its appearance. Every surgeon has had cases in which contrary to expectation the patient has recovered. At times apparently moribund patients recover even after operation has been refused because there seems no hope. This recovery is usually due to the fact that Nature provides an issue for the pus by some method of spontaneous evacuation. In general, however, a case of appendicitis can never be operated upon more safely than when it is first recognized.

Recuperative Power.—The study of the changes that take place in an appendix when natural forces are working for its removal, while Nature is trying at the same time to protect the individual from harm, are most interesting. In the formation of adhesions and of newly-formed connective tissue generally, cells fall into line for reparative purposes with a unanimity and a helpful cooperation that seem little short of intentional. More important processes within the body share this same tendency to accommodate themselves to changed circumstances in pathological conditions. The reversal of peristalsis, which takes place whenever occlusion of the intestines occurs, is a striking example of this conservative accommodation of means to other ends than those for which they were originally intended. For forty years or more, perhaps, persistalsis has always acted downward and now, in the hope of preventing fatal accumulation of material, the process is reversed. The mechanism for reversal is as intricate and requires as much intention as does, for instance, the reversal of a steam engine.

Cell Instincts.—There is no doubt that to man is arrogated too much superiority to the individual cell. It is the custom to say that animals have instincts and to explain many of the things which seemingly require reasoning powers to the presence of this faculty. It is a method of explaining animal intelligence without a resort to mental qualities. Cells undoubtedly possess instincts that are not unlike those of the animal and that are at least utterly inexplicable so far as we have been able to study them. The case of phagocytes, for instance, who fall on the battlefield of the inflammatory disturbance, unselfish martyrs to the cause of protecting other cells and through them the higher organism to which they all belong, are the best example of this. Further study will undoubt-

edly reveal many things that are now mysteries in these cell processes and give higher ideas of the wonderful work they do.

Diagnosis of Appendicitis.—Despite all study of the disease the diagnosis of appendicitis is not yet an absolutely soluble problem. There are cases in which renal calculus, for instance, may simulate every symptom of an appendicitis and in which the only hope for differential diagnosis is the finding of a few blood-cells in the urine after careful microscopic examination. Even so ordinary a disease as typhoid fever may for some days simulate appendicitis so closely as to make diagnosis practically impossible. In this case the presence of leucocytosis is important. In typhoid fever, if there is no ulcerative process, as there usually is not at the beginning, there will be no leucocytosis. The number of white blood-cells will soon be recognized as an important diagnostic point in other regards. If marked leucocytosis is present in appendicitis a favorable prognosis exists, however serious the symptoms may be.

Extra-Appendiceal Symptoms.—The presence of a collection of purulent material in and around the appendix often gives rise to symptoms in parts of the body far distant from the appendix. Arthritic symptoms due to the presence of a subseptic state, a mild pyemia, have already been spoken of and are sometimes a very interesting feature of certain cases. The mimicry of other intestinal diseases is quite common. Ordinary colic is usually appendicitis. Colicky symptoms in other parts of the intestinal canal may owe their origin to the reflex irritation of the pathological condition of the appendix, or to the presence of irritating material in the vascular system of the intestine. A very curious set of symptoms are those which in appendix cases seem to point to the existence of an ordinary indigestion, capricious appetite and recurrent pains after eating being prominent symptoms.

Significance of Appendicitis.—It is now much better realized than formerly. Life insurance companies, for instance, now refuse to take risks on the lives of patients for one year after a first attack of appendicitis, and will not insure until the appendix is removed if there has been more than one attack. Truth always comes letter by letter in medicine, but the subject of appendicitis has been lifted out of the opprobrium of the past. The improvement has come not alone in knowledge of the pathology and etiology of the disease, but also in its therapeutics and in the indications for treatment furnished by special symptoms. The old reproach, "And have some doctor shake his learned head and give the ill he cannot cure a name," no longer comes home to us, in regard to appendicitis, as it did in the past.

Medical Board of City Hospital.—The following officers were elected at the annual meeting: President, Dr. Edward S. Peck; Vice-President, Dr. D. Hunter McAlpin, Jr.; Secretary, Dr. Charles L. Gibson; Chairman of the Committee of Inspection, Dr. Charles C. Ransom.

BOOK REVIEWS.

Duane's Medical Dictionary. A Dictionary of Medicine and the Allied Sciences. By Alexander Duane, M.D., Assistant Surgeon to the New York Ophthalmic and Aural Institute. Lea Brothers & Co., Philadelphia and New York.

The man who has occasion to examine medical students, or, more especially, advanced practitioners who apply for State licenses, is impressed always with the almost universal lack of accuracy both of statement and of use of words. Every effort that tends to direct the attention of medical men to accuracy of definition and makes it easy for them to acquire it is to be cordially welcomed. Duane's dictionary fulfils this to a marked degree. In this last edition the work has been enlarged to include pharmacy, dentistry, and veterinary science. Under the principal diseases a concise sketch is given of causation, symptoms and treatment; under the more important organs an outline of their structure and functions, and under each drug an account of its action, uses, preparation and dosage. A practical test, by daily use during the past three months, demonstrates that the work is reliable, complete, convenient and in every way satisfactory.

Cancer of the Uterus, Its Pathology, Symptomatology, Diagnosis and Treatment. By Thomas Stephen Cullen, M.D., Associate Professor of Gynecology in the Johns Hopkins University. Illustrated by Max Brödel and Hermann Becker. New York: D. Appleton & Co., 1900.

The steady and rapid increase of cancer is arousing renewed interest in the study of its nature, its methods of extension, and its etiology. The contribution that Dr. Cullen has made to the science and literature of this subject forms the most complete and satisfactory work in this field that has ever been presented to the medical profession. Dr. Cullen has no new theory to expound regarding the primary cause of the disease, but he presents in the book before us all of value that is known upon the subject. In addition to these is given a most complete and careful record of his clinical and pathological study of all the cases of cancer of the uterus or any disease that might possibly be confused with cancer that have come under observation at the Johns Hopkins Hospital during the last seven years. The book is of great value to the pathologist, to the family physician and to the surgeon. The author bases his work upon the hypothesis, dictum or fact, that the microscope is the final arbiter in making a differential diagnosis, and specific directions are given for the preparation and the examination of scrapings from the endometrium, and the securing and treating of specimens of tissue from all infected areas. The chapters on the early recognition of cancer are so distinct and clear that a wayfaring man, though a general practitioner,

should not err in giving, or directing to, prompt and efficient relief. The descriptions of the latest methods of surgical treatment, the discussion of methods of transmission (implantation) and the judicial consideration of prognosis are of value to the surgeon. The names of Max Brödel and Hermann Becker are sufficient guarantee of the excellence of the illustrations.

Practical Manual of Diseases of Women and Uterine Therapeutics for Students and Practitioners. By H. MacNaughton-Jones, M.D., M.Ch., Master of Obstetrics, Royal University of Ireland; President of the British Gynecological Society, etc. Eighth Edition. New York: William Wood & Company.

This well-known manual appears in its eighth edition pregnant with new matter. The author makes extensive notes on the management of the various operations, omitting none of the details the knowledge of which is ordinarily presupposed, but which the young practitioner or student has not yet learned by practical experience. At the same time the text is elucidated by numerous excellent original illustrations, which are a prominent feature of the work. Tables of etiology and symptoms adapt the book to the student's demands, but it is to be regretted that in treatment many methods are outlined without any indication of the author's preferences. Chapters are devoted to asepsis and antisepsis, surgical instruments, sutures, arrangement of operating room, etc., which belong rather to works on general surgery. In the medicinal treatment we are surprised to see mentioned and recommended not a few proprietary articles of presumably unknown composition. Chapters on the rectum and urinary organs add to the value of the book and make it as complete as one could find in such compact form.

The Law in Its Relation to Physicians. By Arthur N. Taylor, LL.B., of the New York Bar. New York: D. Appleton & Company.

The object of this book is to place within the reach of the physician a systematic treatment of those questions of law which affect his ordinary professional work, and to explain the general principles upon which his rights are based. It is not a treatise on medical jurisprudence, but rather a series of talks on the responsibilities of physicians, their control over patient, their right to compensation, and their duties under the law as medical men. Some of the questions discussed are the liability of master for attendance upon servant, of one person who calls a physician to attend another person, of physician in cases receiving treatment free, and in operations of necessity. Cases and court discussions are introduced in brief to illustrate in a practical way the exact meaning of certain laws. Usually the general nature of the query precludes consideration as to individual State laws, but where these laws differ materially they are compared and commented upon. The style smacks of the legal, but it is agreeable, clear, and not technical. An extensive index adds to its value.

A Treatise of Diseases of the Nose and Throat. By Ernest L. Shurly, M.D., Vice-President and Professor of Laryngology and Clinical Medicine, Detroit College of Medicine, etc., etc. D. Appleton & Company, New York.

Aiming at thoroughness and comprehensiveness in his treatment of each subject the author has treated diphtheria and tuberculosis much as they would need to be treated in a work on general medicine, simply because they had a claim to consideration as nose and throat affections. This thoroughness pervades the book. It skillfully summarizes the history. It arrays the *pros* and *cons* in etilogy and pathology, giving all views a fair chance to be heard and prefers to leave decisions to the readers, though occasionally it ventures a "not proven," as in the case of identity of causative agent in tuberculosis and lupus. It is with regret we notice that authors are credited with views without reference to the literature whence the views are obtained. We fully appreciate what a huge bibliography would have been needed for this book, since the author seems to have consulted everything written on the subjects treated. Yet, a work of this kind in our times is signally deficient that omits such a bibliography, since readers often wish to consult the originals, read them *in extenso* and along with their content. Otherwise, we must speak commendably of this book, written in good language, racily, thoughtfully and with full appreciation of the importance and setting of the various subjects. It has the true spirit of scientific investigation in all questions of research. It presents many methods and hints at the best. The author's grasp of general medicine is evident from the point of view from which he considers his specialties. This vouches for the helpfulness of the book to the general practitioner. He might profitably have said more about immunization when he said so much that was valuable about diphtheria; and he might profitably have said more about the selective influence of *la grippe* for the nervous elements when he said so well so much else of value about it. The book demonstrates its value to us by the forceful and virile thoughts it gives us, instead of mere recitations of facts and methods, necessary as these are and faithfully as they are given. It is alive with the vigor and restlessness of modern medical progress. The make-up is fairly good. The photo-engravings illustrate and teach how intubation is done.

Speech Hesitation. By E. J. Ellery Thorpe. E. S. Werner Publishing & Supply Company, New York.

Mrs. Thorpe's book treats the subject of speech hesitation as a fault that is in practically all cases amenable to correction. So many of these cases seem hopeless and their infirmity inflicts such a degree of suffering that attention can not be called too often to possibilities of cure under proper methods of respiratory regulation. Some of the cases that have been im-

proved by the method suggested here are sufficiently striking to encourage further trials to cure no matter how hopeless the case may seem. There is, of course, a large personal element in any successful method of treating these cases, but valuable points can be gathered from others' experience by those who are interested in the subject and hence the usefulness of this manual.

PHYSICAL DIAGNOSIS OF DISEASES OF THE CHEST. By RICHARD C. CABOT, M.D., Assistant in Clinical Medicine Harvard Medical School. William Wood & Co., New York.

DR. CABOT'S purpose in writing this book is expressed very tersely in the preface as follows: "I have written it because I have not been able to find any small work upon the subject which does not contain glaring errors. The correct books are too large. The small books are out of date and repeat such well worn myths as that the aortic second sound is normally louder than the pulmonic sound; that aortic regurgitant murmurs are usually best heard in the second right interspace, that the hypertrophied left auricle can produce dulness and pulsation near the left sternal border, that systolic retraction at the cardiac apex means adherent pericardium, that episgastric pulsation denotes hypertrophy of the right ventricle, etc."

It is clear from this that Dr. Cabot intends his book to be up to date, and it is. For a manual the illustrations are well chosen, though we can hardly say that they are fittingly reproduced. In general the book is very clearly and succinctly written. There is a taking suggestiveness about the style that fits it for the student. Without any appearance of piling up erudition a large amount of valuable practical medical knowledge is conveyed.

GUY'S HOSPITAL REPORTS. Vol. LIV. being Vol. XXXIX. of the Third Series. J. A. Churchill, Great Marlborough Street. London, 1900.

ONE can always be sure of finding good things in the Annual Report of Guy's. This time Dr. Frederick W. Taylor has a very interesting article on spleno-megalic cirrhosis of the liver. As this involves a discussion of the pigmentation of the skin in hepatic disease and also the significance of the stunting of growth which often causes club fingers, its interest can be understood.

Dr. W. Hale White devotes fifty pages to a discussion of diseases of the pancreas. This sums up very well our present knowledge of these obscure conditions and shows how much has been accomplished in very recent years to throw light upon this neglected organ and its affections.

Dr. G. E. Halstead has an article on "Some points in the treatment of acute infantile diarrhea with some hints for the young practitioner," that is very helpfully suggestive. This from the end of the article is good: "At the close of a series of lectures on the use of acids and alkalies an intelligent student went down to the lecturers table and quietly asked, 'But, Dr. M., when *would* you give acids and when *would* you give alkalies in stomach trouble?' Dr. M.'s reply was: 'Mr. W. if you have really followed my lecture as closely as you appear to have done you will have perceived that I am quite unable to tell you.'"

Dr. Halstead's summary of the treatment of infantile diarrhea is: "Diarrhea is due to something in the diet. Empty the bowels and keep them cleansed, preferably by castor oil. Energetically treat the collapse and do not trouble about the number of motions. Do not stop up the bowels by astringents and opiates. Give hardly any food for a few days, begin with white of egg solution in teaspoonful doses every half hour. If the baby is too hot, cool it. If it is too cold, warm it. If it is thirsty and not sick, give it water. Keep it in the fresh air all day long."

THE PREVENTION OF VALVULAR DISEASE OF THE HEART. By RICHARD CATON, M.D., Emeritus Professor of Physiology, University College, Liverpool. C. J. Clay & Sons, London.

THE author says in the preface that valvular disease of the heart has always been and still remains one of the opprobria of medicine. His object here has been "to promote the detection of the malady in an early stage, to study the commencing pathological changes, to investigate the manner in which in a few cases a natural arrest of the disease is brought about, and to seek by artificial means to render this arrest in the early stage usual rather than exceptional." On these very interesting themes he has made an extremely suggestive book.

The methods of treatment employed by the author are first absolute rest when the heart lesion is recent. This he considers the most essential therapeutic measure. Second, treatment by stimulation of trophic centers. This is done by counter irritation over the precordia. The third measure is the use of absorbent drugs. Of these sodium iodide is given the preference. By these means the author has accomplished certain definite results in eighty-six recent cases. His results include a number of cases in which heart murmurs with some functional symptoms of organic heart disease disappeared during the course of the treatment. The book bears the stamp of serious practical clinical work and deserves the careful study of those who are interested in the cure of heart diseases.

THE ART OF BREATHING AS THE BASIS OF TONE PRODUCTION. By LEO KOFLER. E. S. Werner Publishing & Supply Co., New York, 1900.

THIS little book of 250 odd pages is of interest to the physician for two reasons. First, because it treats the subject of faulty articulation from the standpoint that it is curable by the proper management of the breathing. Lisping and stuttering while dependent very often on congenital defects can be overcome by proper training.

Hints as to how this training should be instituted are here given in a very practical way. The second medical interest in the book comes from the fact that so many people can, or think they can, sing. Many singers adopt an entirely faulty method of tone production and this is the basis of many a form of chronic laryngitis. The question of the proper method of tone production as it is treated here in practical fashion by Mr. Kofler, who is the organist and choirmaster of St. Paul's Chapel in New York City, can scarcely fail to be helpful to the general practitioner who has such patients to treat.

A Text-Book of the Practice of Medicine. By James M. Anders, M.D., Ph.D., LL.D., Professor of the Practice of Medicine and of Clinical Medicine in the Medico-Chirurgical College, Philadelphia. Fourth Edition. W. B. Saunders & Company, Philadelphia and London.

Conciseness, clearness and systematic arrangement combined with accuracy, make a work on medicine a favorite with both the busy practitioner and the student. And it is perhaps these qualities that have required a new edition of this book within a year. The author has culled much of his material from other writers, has boiled it down and sorted it out, and to it has added ideas and criticisms of his own. The section on Diseases of the Digestive System has been extended and brought into line with what recently introduced methods of diagnosis have taught us. Sprue, ileo-colitis in children, and acute cholecystitis have been entirely rewritten, and the animal parasitic diseases, intoxications and other chapters have been revised. Historical matter is omitted and treatment is outlined in a brief but efficient manner. Quantities are given in both the English and the metric system, the latter suffering from a too literal translation, which makes the figures sometimes impracticable for prescription writing. Compactness enables the author to get a great amount of valuable matter into a single volume.

Cancer of the Stomach, a Clinical Study. By William Osler, M.D., and Thomas McCrae, M.B. (Tor.), of the Johns Hopkins Hospital. P. Blakiston's Son & Co., Philadelphia.

This is the fourth of that delightful series of special works begun by William Osler, the preceding ones of which are on angina pectoris, abdominal tumors, and chorea. The authors have made a detailed study of 150 cases at the Johns Hopkins Hospital diagnosed as cancer of the stomach. In the etiology an interesting relation is shown with tuberculosis and the use of alcohol, while previous stomach trouble is found to render an individual not more prone to cancer. The occurrence of the disease in the young, latent cancer, and the blood examinations form chapters which have already been published in brief in the journals, but the greater portion of the book is devoted to a study of the tumor and its symptoms. Vomiting, pain, loss of weight and strength, the condition of the various organs, the examination of stomach contents, and the secondary symptoms such as metastases, perforation, jaundice, ascites, and edema are all considered in detail. There is a chapter on pathology, and one on treatment, the latter of which is particularly concise and satisfactory. The book should be in the library of every physician and surgeon. The illustrations add to the value of the work.

Hernia. Its Etiology, Symptoms and Treatment. By W. McAdam Eccles, M.S. (Lond.), F.R.C.S. (Eng.). Wm. Wood & Co., New York.

Inguinal and femoral herniæ are chiefly considered in this volume, the other forms, *e.g.*, umbilical, ventral, obturator, sciatic, etc., being dismissed with a very brief description.

The etiology of hernia is given at some length, some of its causes being ascribed to heredity, age, sex, and form, length and prolapse of mesentery. The clinical conditions of hernia are divided into reducible, irreducible, inflamed, obstructed and strangulated. The symptoms of all these conditions are carefully noted and in the case of all reducible herniæ, the treatment by truss is given in every detail. A form of truss is even advised in certain cases of irreducible hernia. Strangulated hernia receives considerable attention, particular emphasis being laid upon the symptoms and diagnosis. Prolonged taxis is discountenanced and early operation is advised; a radical operation should be done if the strangulated area can be replaced in the abdomen and the condition of the patient will allow of it. The radical operation advised in cases of inguinal hernia leaves the cord in the inguinal canal. The aponeurotic fibers of the external oblique are divided up to the internal ring, the sac tied off flush with the peritoneum and the internal oblique and transversalis united to the inner half of Poupart's ligament. Buried sutures of silk are used.

The operations of Bassini and Halstead, so popular in this country, are accorded only a few lines for their description.

Femoral hernia is well described and its palliative and operative treatment indicated. In fact the whole volume deals principally with the palliative treatment by truss.

BOOKS RECEIVED.

Mutter Lectures. 1900. By Dr. John B. Roberts. 12mo, 53 pages. Illustrated. Philadelphia.

Thomas Sydenham. By Dr. Joseph Frank Payne. Masters of Medicine Series. 8vo, 264 pages. Illustrated. Longmans, Green & Co., New York.

Appendicitis and its Surgical Treatment. By Dr. Herman Mynter. Third Revised Edition. 8vo, 231 pages. Illustrated. J. B. Lippincott Company, Philadelphia and London.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVIII. NEW YORK, SATURDAY, JANUARY 19, 1901. No. 3.

ORIGINAL ARTICLES

CONCLUSIONS FORMED AFTER SIX YEARS' EXPERIENCE WITH THE ANTITOXIN TREATMENT OF DIPHTHERIA.

BY HENRY F. KOESTER, M.D.,

OF NEW YORK.

ABOUT six years ago, when the reports of Behring's observations on the antitoxin treatment of diphtheria began to reach this country, the medical profession probably was called upon to treat no pathological condition which so baffled the skill of its members as the affection now under consideration.

Mild cases in which the disease manifested itself by perhaps a slight tonsillar exudation, attended with slight, if any, constitutional symptoms, usually responded to the ordinary treatment then in vogue, consisting of the application of caustic or antiseptic remedies to the affected surfaces, with perhaps the addition of drugs or stimulants, directed toward sustaining the life of the patient until the disease was ended. Indeed, it had even then come to be considered that the administration of stimulants, preferably alcoholic, was productive of the best results obtainable. Some even went so far as to recommend and put into effect the use of stimulants to the point of intoxication. In malignant cases, as they were then called, the same plan of treatment was adopted, but the results were anything but gratifying; the mild cases would get well any way, while those of the severer type owed their recovery, which occasionally took place, to the intervention of a Divine Providence.

The situation was such that Behring's observations found the majority of medical men in a condition eager to grasp anything which offered the prospect of better results. The hope engendered by his writings gave way to a feeling of positive assurance, as patient after patient recovered under this plan of treatment, that the profession was at last in possession of a remedy for diphtheria which offered some hope of intelligent medicine. Nor have this hope and assurance grown less as time has elapsed; but, as the experiences of observers have continued to add testimony to its positive efficiency, the time has at last arrived when we feel that, given a case of diphtheria sufficiently early in its course, we have in antitoxin a remedy at our command which is positive in its effects. Although this is now the accepted belief, there are a few who still remain skeptical. The writer feels that if by a narration of his individual experience, extending over a series of 170 cases in private practice, to say nothing of the privilege he enjoyed in common with other attachés of the Health Department of the City of New York, he can do anything to remove the skepticism of a single observer with regard to the value of antitoxin as a remedy for diphtheria, his justification for such a course is most ample.

Diphtheria may be truly said to be a disease of childhood, for of the 170 cases forming the subject of this article but five, or about three per cent., occurred in adults. The treatment formerly employed was especially distressing when applied to children. It necessitated the continued exhibition of brute force, and even when we felt that we had mastered the disease, as far as its outward manifestations were concerned, we did not feel for some time that all danger was passed. It was not an uncommon experience to carry a child through a long and exhausting sickness, which was often a struggle from beginning to end, only to have it finally succumb to a sudden attack of cardiac paralysis. Now, when called to a child afflicted with diphtheria during the first forty-eight hours of the disease, the writer feels justified in promising the family and friends that, with the antitoxin treatment properly applied, recovery will take place inside of forty-eight hours more.

This leads us to the consideration of what constitutes the proper application of the antitoxin treatment. We have seen a patient with diphtheria treated with antitoxin by one who was not familiar with its use, into whom the remedy had been injected with an ordinary hypodermic syringe, necessitating numerous injections of a small quantity of the serum, thus subjecting the patient to unnecessary torture and producing anything but satisfactory results.

Antitoxin, to obtain its best effects, must be used fearlessly and in quantity sufficient to be effective, which is never less than 2,000 units, and that in very mild cases. In severe cases at least 3,000 units must be used, and this dose repeated in from twelve to twenty-four hours. Antitoxin in itself, contrary to the expressed belief of some observers, never does any harm.

It is the opinion of the writer that antitoxin and an appropriate syringe should be a part of every practising physician's armamentarium—as much so as a pocket-case and a hypodermic syringe—and that he should never be without them in his pocket or instrument-case, when called to see a patient about whose condition he knows nothing. When called to see a child sick with an ailment which may or may not be diphtheria, the first step in examination is to look at the throat. If any suspicion of exudation is present an injection of antitoxin should be the next move, after which a culture be taken. If a subsequent examination proves the case to be one of diphtheria, the patient has been put in the best possible condition to combat the disease; if the bacteriological test proves that you were mistaken, no harm has been done.

One of the most important facts to bear in mind in the use of antitoxin is that the dose is to be regulated by the severity of the disease and the length of time the patient has been ill, and not by the age of the patient. There may be some exceptions to this; but it is a safe rule to follow, whether we meet with diphtheria in a child of one year or five years, that the only features to be regarded are the severity and length of the disease. Even when the age of the patient is more than five years, it will not be necessary to increase the dose of the remedy very much. Two thousand units is the smallest dose that should ever be given, and then only in very mild cases of tonsillar diphtheria, excepting in cases of children under one month old. When the disease has invaded the uvula and pharynx, as evidenced by the exudation on these parts, 3,000 to 4,000 units should be the initial injection. Should the nares also be involved, my invariable rule is to give from 4,000 to 5,000 units at my first visit. It is extremely difficult to ascertain just how much membrane there may be in the posterior nares, and, if its presence can be determined in this situation at all, it is better to give the patient the benefit of any doubt we may have as to its extent and give a large injection immediately.

In cases of diphtheritic croup, large doses, say from 4,500 to 6,000 units, should be given, and we should also be ready to intubate at a moment's notice. In intubated cases the tube can be removed in four to five days. Should stenosis recur, the latter is not due to the diphtheritic membrane, but either to granulations or spasm of the larynx. When, in addition to laryngeal diphtheria, there is an exudate in the pharynx and tonsils, one should be governed by the condition of this membrane as to the necessity of repeating the injection. If the pharyngeal exudate disappears after the first injection, it is safe to infer that the laryngeal exudate will do likewise, and a second injection will not be necessary. In all cases, whether pharyngeal or laryngeal, the injection should be repeated in from twelve to twenty-four hours, depending on the condition of the patient. In cases of mixed infection, or so-called septic cases, the initial dose is from 5,000 to 6,000 units, repeated in twenty-four hours. It is not an uncommon experience to find, in a family in which one child has diphtheria, other children who apparently are not ill, but have colds in the head. One child may have a running nose, another a mucopurulent discharge from the eyes; and a bacteriological examination will reveal the presence of the diphtheria bacilli. In these children a single injection of 2,000 units of antitoxin will produce marvelous results. As a rule, this single injection will stop the discharge without further trouble. In many cases of croupy cough (membranous croup), even cases that have been called pertussis, it will often be found that the bacilli are present, and an injection of antitoxin will stop the trouble.

It is not necessary that the injection should be made at any particular point, but there are reasons why certain parts are preferable to others. It is not an uncommon practice to choose the muscles of the back, but it is my custom to make the gluteal region the site of injection. If the assistant places the child over one knee, face down, and with his free leg over the patient's, it is very easy to hold the child firmly, and the gluteal muscles offer a convenient place for operation; then, too, no matter how much the patient may struggle the operator need have no fear of puncturing or wounding other important parts. This cannot be said of injections over the back, chest or abdomen, as it would not be difficult if the patient struggled violently, as they sometimes do, to puncture the pleura or peritoneum. Moreover, a large injection over the chest or abdomen will cause a swelling which often disappears very slowly, whereas in the gluteal region this is not the case, especially if the needle is carried deep into the muscle.

One of the most valuable features of the antitoxin treatment of diphtheria is its use in immunization. In large families in tenement-houses, when isolation of the afflicted person is impossible, unless removed to a hospital, an injection of the remedy into those not infected will prevent the spread of the disease. In former days, when diphtheria was treated empirically, it was not an unusual occurrence to have several members of a family die of diphtheria before its course could be checked; but now such a condition is almost, if not entirely, unheard of. The reports of physicians in institutions in which children are kept, and from medical men generally, seem to fix the immunizing dose at from 150 to 300 units; but it has been the writer's uniform custom to give from 300 to 500 units in tenement- and flat-house districts where children cannot be closely watched and where isolation cannot be practised. My experience with the immunizing power of antitoxin has been quite large, embracing a series of nearly 1,800 cases in tenement-house practice. In only four of these cases was a membrane produced within from twelve to thirty days after the injection. In only one of these was the membrane which appeared thirty days afterward due to true diphtheria; one was due to follicular tonsillitis and the remaining two to streptococcus infection. Never have I seen any complications or sequelæ follow the use of antitoxin as an immunizing agent, excepting the occurrence of an urticaria-like rash, and even this does not occur in more than ten per cent. of the cases and lasts only a day or two.

Passing now from the consideration of the simple antitoxin treatment and giving attention to the question of whether it is necessary to use any other treatment in connection with it, it may be stated that this must be determined by circumstances. Antitoxin is a specific in diphtheria and when the disease is mild or in its earliest stage, the membrane thin and not covering a large surface, it is not necessary to do more than give one injection, depending on the antitoxin to cure the disease. When, however, the disease has made more progress and a putrefaction change has oc-

curred, accompanied by foul-smelling discharges, it will then be well to employ some measure to destroy the odor and to keep the parts sweet and clean. For this purpose I have employed a neutral preparation of peroxide of hydrogen, mixed with double or three times its volume of water. I have also used a saturated solution of boracic acid, or a normal salt-solution; but it is my belief that the best results are obtained with peroxide. These solutions should not be sprayed in the throat, but should be thrown in with a long-nozzled, hard-rubber syringe holding an ounce, after depressing the tongue with some force against the pharynx, so that the liquid washes not only the tonsils, but the pharynx and posterior nares as well. This should be repeated every hour or two. It is very important that these solutions should be neutral. Some of the preparations of the peroxide of hydrogen are acid and will crack the mucous membranes of the lips and mouth. This is very distressing to the patient and interferes with the ease with which these washings can be made and also with the taking of proper nourishment.

In nasal diphtheria the nose should be irrigated, preferably with a saturated solution of boracic acid. On the first day of the disease this irrigation, which should be done every three or four hours, without force, perhaps with a fountain syringe, is for the sole purpose of keeping the parts clean; but after the second or third day, when the membrane begins to exfoliate, an occasional more forcible injection with a ball nasal douche will often detach membrane which was perhaps only partly separated. The writer has frequently been able, in this way, to detach large masses of membrane, sometimes clearing out both nostrils and the posterior nares with one of these forcible injections. By removing these membranes it is made possible for the patient to close the mouth and breathe through the nose. Care should be taken that nothing is forced into the Eustachian tube, this is avoided by instructing the patient to keep the mouth open. When, because of the youth of the patient, this cannot be accomplished by instruction, a gag of some kind should be placed between the teeth, and the mouth kept open during the douching. But should the liquid be forced into the Eustachian tube, which is not likely to occur as the swollen mucous membrane will tend to prevent it, even this would be preferable to having the foul, putrefying mass retained and the patient poisoned thereby, besides polluting the atmosphere and making the danger of infection greater to the attendants and other members of the family.

This is all that need be done in the way of local treatment; the administration of astringent or cauterizing agents cannot be too strongly condemned. The internal treatment is very simple and consists in the administration of strychnine in essence of pepsin, or some other vehicle. This is given simply as a cardiac tonic and to aid digestion. The tincture of the chloride of iron and chlorate of potash are to be condemned as they tend to derange the stomach and cannot in any way be productive of anything but harm. Alcoholic stimulants are indicated in only very severe cases.

The after-treatment consists in administering remedies directed toward hastening convalescence—such as tonics, preferably syrup of the iodide of iron.

The feeding is most important, and as the appetite is generally not good, I have come to believe that the best results can be accomplished by catering to the patient's fancy. Frequently the proper nutrition has been afforded by feeding a child on ice cream. Whatever beef extracts, liquid peptonoids, milk, or other foods are used, what is desired is to sustain by proper nutrition, until such time as the disease ends and the normal appetite returns. To accomplish this purpose every practitioner of experience will have his own methods.

In feeding intubated cases, as the toxemia is not apt to be so great, either because the membrane is not so extensive or the larynx does not absorb the poison rapidly, it is my custom to give internally nothing but water for twenty-four hours. This is done because of the danger of occluding the tube with particles of food or curds of milk; besides which the mouth is kept cleaner. After twenty-four hours, when the child has become more accustomed to the tube, ice cream, canned condensed milk, and thick gruels are given. One must use his own judgment in the matter of feeding. Some children are averse to taking nourishment of any kind, but, if patient search is made, some one thing will be found that the child will take with pleasure. I recall more than one case in which, after intubation, children have lived for several days on beer, taking it with avidity and rejecting everything else. I do not especially recommend beer as an article of diet for children with diphtheria, but simply mention this, to show how sometimes the unthought-of thing will serve the purpose in an emergency. When children refuse everything, feeding through the nose is preferable to rectal alimentation.

I have said nothing about calomel sublimation and other methods often employed as accessories, because I do not believe in them. Calomel sublimation, especially, I think cannot be too strongly condemned. I believe it irritates the mucous membrane and renders the patient more liable to complications, such as bronchitis and pneumonia, besides being productive of salivation in the nurses and discomfort generally. Steam inhalations to be effective require that the atmosphere should be saturated with moisture. This necessitates the closing of windows and doors, raises the temperature of the room, and prevents the free supply of oxygen, which it is necessary to have in order to secure good results

Membranous croup is almost always diphtheria, and after intubation should be treated as such. Patients with croup are often found in whom there is no membrane at all in the pharynx,

and a culture does not reveal the true bacilli. But if intubation is practised and a culture taken from the first expectoration after the tube is in place, the Klebs-Loeffler bacillus will invariably be found. This is a fact to which I have never seen an exception.

The character of the disease is altered when diphtheria is complicated with other affections, as scarlet fever, measles, whooping-cough, etc. It is my invariable custom, when any of these latter affections show membrane, to inject from 2,000 to 2,500 units of antitoxin at once, before taking a culture. Indeed, there are many physicians who invariably employ antitoxin in their scarlet-fever cases, some even going so far as to say that it affects the course of the disease favorably.

Whether this is so or not, and it has never been authoritatively stated that such is the case, one thing is certain, namely, if antitoxin is used in these cases from the beginning and an antiseptic or neutral solution of hydrogen peroxide used in the throat, one will never have diphtheria complicating scarlet fever; and, further, if the antitoxin does not affect the fever favorably, it is safe to say, and say positively, that it will not affect it unfavorably.

Another dreaded complication, and one which not infrequently carries off patients after intubation, is bronchopneumonia. Some believe that this is traumatic and is due to particles of food passing through the tube, or even to the irritation of the tube itself. Be this as it may, I believe that this condition can sometimes be prevented, if nothing but water is given during the first twenty-four hours. I believe, also, that careful examination of the patient will often find the right heart weak and overdistended with venous blood.

By careful stimulation of the heart by means of aromatic spirits of ammonia, strychnine and nitroglycerin, and by careful reduction of the temperature by cold sponging, and not by means of the various coal-tar preparations, bronchopneumonia can often be prevented and a favorable termination of the disease brought about, without further medication.

The sequelæ most commonly met with in diphtheria treated with antitoxin are a rash and occasionally joint pains. The treatment of the rash is symptomatic—relieve the itching, when the rash is in the form of urticaria, by cold sponging with alcohol and water. This will also reduce coexisting elevation of temperature. The joint pains are treated by rest in bed and administration of the salicylates.

I should like to say a few words, while on this subject, about the probable cause of the rash which sometimes follows the injection of antitoxin and which so often resembles urticaria. Tilbury Fox gives as one of the causes of urticaria "the circulation of acrid effete products in the blood." It may be supposed that a child with diphtheria has a certain amount of excrementitious matter in the blood, which the kidneys, the lungs and the skin will eliminate in the ordinary course of events; indeed, it is not necessary to suppose the child to have diphtheria or any other disease, as these excrementitious matters are being eliminated all the time, and continue naturally up to a certain point.

But it is well known that there is a limit to the excreting power of these organs, and when the blood is overcharged with these effete products an explosion must take place somewhere and, as the skin is the greatest of the excreting organs, it is apt to occur there. Some people get urticaria after eating certain articles of food, because the skin is being called upon to excrete more than it is able to do with ease. Supposing that into the blood, already charged with these effete products, a certain amount of horse-serum, also charged with the hippuric acid and other excrementitious products of the horse, is injected, the consequence will be that the human blood becomes overcharged with this excess of effete matter, and the kidneys and lungs, being incapable of eliminating more than a certain amount, the skin is called upon to dispose of the rest. It does it, but at the same time presents this condition of urticaria. This being the case, it has occurred to me that if the excrementitious salts held in solution in this horse-serum could be eliminated, the occurrence of the rash might be prevented.

I believe this could be accomplished by the process called dialysis, the only question being, Would the antitoxin in the serum be sufficiently soluble to be separated also? I make this suggestion for what it is worth, and leave it to the chemist and physicist to determine what its value may be.

In conclusion let me say (1) that antitoxin is a positive cure for diphtheria, when employed in sufficient quantity and sufficiently early in the disease; (2) that even when employed too late in the disease to produce its specific action, it cannot under any circumstances be productive of harm; (3) that when used before the invasion of diphtheria, antitoxin possesses a positive immunizing power which lasts about thirty days.

A good deal has been said and written about the failures of antitoxin, but in none of these cases has it ever been stated what quantity of antitoxin was employed, how early it was given in the disease, what complications existed before using, or how other medication as, for example, large doses of bichloride of mercury, may have contributed to the unfortunate ending. There is antitoxin which is not of standard strength and has little or no antitoxic value—it may be too old, or it may have been obtained from a sick horse—but if the practitioner of New York will use the antitoxin prepared by the New York Health Department, which is always as it is represented to be and always at his command, and use it fearlessly and invariably in all cases of diphtheria, *whether mild or severe*, he will get good results and have no occasion to regret its use.

336 East Eighty-fourth Street.

PROBLEMS IN THE ETIOLOGY, DIAGNOSIS AND TREATMENT OF TUBERCULOUS DISEASE OF THE UPPER AIR-PASSAGES.*

BY JONATHAN WRIGHT, M.D.,
OF BROOKLYN, N. Y.

FROM the earliest times to the present the idea has always existed, and it has occasionally been the accepted doctrine, that consumption is infectious. The historian from whom I quote[1] adds the remark, "Undoubtedly a susceptibility is always associated with it." This perhaps is as good a synopsis of a modern thesis on the etiology of tuberculosis as can be given in a few words. It is with the details of the question we are at present concerned. The question of the etiology of tuberculosis in general does not enter the province assigned to me in this discussion. I have many times protested against the tendency to consider the tubercle bacillus as the sole agent in the production of tuberculosis. This tendency has arisen from the fact that it has been convenient to classify disease, in the last few decades, on the basis of etiology, rather than on that of pathology or on the still earlier basis of symptomatology, but, after all, the etiology and pathology of one generation is apt to become the pathology and symptomatology of the next. This tendency is still more due to the fact that the tubercle bacillus is the tangible factor while the others, although quite as important are as yet imperfectly apprehended. The problem which now confronts us in the study of the causes of tuberculosis is the necessity for finding a method, perhaps in organic chemistry, by which we may investigate those factors which render the morbific influence of the tubercle bacillus an efficient one in the production of disease in the animal economy of its host. The discussion of this also lies beyond the limits assigned to me, though these factors enter quite as largely into the real etiology of the local disease as does its bacillus.

It is unnecessary for me to remind you how frequently the presence of the tubercle bacillus has been demonstrated not only on the surface of mucous membranes, especially of the upper air tract, but in the internal organs and the lymphatic system of man, without the production of that congeries of lesions and symptoms which we indicate by the term tuberculosis.

In examining microscopically more than a hundred specimens I have failed to find either the tubercle or the tubercle bacillus in ordinary hypertrophy of the lymphoid material of the throat. While I unhesitatingly deny that the tubercle bacilli are ever the cause of large tonsils and adenoids, it is not alone on account of this failure to find them on my part that I am disposed to doubt that this overgrowth of tissue is the *chief* pathway by which the tubercle bacillus enters the organism. Others have found them. From a total sum of nearly a thousand specimens of tonsils and adenoids examined the ratio of 5 per cent. has been deduced[2] as the proportion of latent tuberculosis in them. I have elsewhere[3] entered fully into the reasons why I am disposed to doubt the reliability of these statistics, and the repetition of them here is unnecessary. However, in the face of all this conscientious work by many observers, it is impossible to deny that hypertrophied lymphoid tissue may absorb from its surface the tubercle bacillus deposited there by the passing air-current and the food. Furthermore, although the experiments of Hodenpyl[4] led to a contrary inference, the more recent investigations of Goodale[5] and Hendelsohn[6], I think, have set at rest the question as to the power of the lymphoid tissue to take within itself inorganic particles placed on its surface. It does not seem any possible violation of close scientific reasoning to venture the belief that they may act in the same way toward the tubercle bacillus. While I believe the ratio of 5 per cent. too high for the occurrence of the so-called latent tuberculosis, I am not at all disposed to doubt the occurrence of latent tuberculosis of the tonsils in a smaller and as yet undetermined ratio. But if we have very numerous researches upon which to form an opinion as to the part played by the abnormal hypertrophy of the surface lymphoid tissue, singular to say we have nothing to base our opinion upon as to the part played by the surrounding normal mucous membranes of the nose and throat. Since their chief function is absorption and transmission, one would suppose that the healthy lymphoid tissue would act more promptly and thoroughly than the diseased structures upon which these observations have been made. Or are we to suppose that tonsils and adenoids have a greater absorbing power than do the normal elements in the mucosa from which they spring?

I think we have good reason for the belief that the tubercle bacillus usually enters the tissues of man before it reaches the stomach by the esophagus or the lungs by the trachea. Many no doubt reach the stomach, but the destructive power of the gastric secretions on the germs in the food is apparently very marked for pathogenic bacteria. We must assume at present that the tubercle bacillus passes into the lymphatics through the mucous membranes of the naso- and oropharynx in a very large proportion of the cases of pulmonary infection. To deny other ports of entry would be dogmatic and is unnecessary. We have no means of venturing an accurate assertion as to the relative frequency of travel along the various possible pathways of primary infection. I think there can be no doubt that the bacillus can pass directly, either by intra- or intercellular channels through the surface epithelium of the mucous membranes, and without a solution of continuity in the stockade of columnar epithial cells. In at least one case of tuberculous laryngitis I have had an opportunity of observing this, as a plate in a former contribution[7] clearly shows. I do not believe that a previous infection by pyogenic cocci is a necessary step in the process, as Lake has intimated[8]. Galen in his time pointed out very clearly[9] that the nose and upper air-passages have

*A contribution to the Symposium on Tuberculosis, held by the New York State Medical Association at its seventeenth annual meeting, New York, October 17, 1900.

for their function not only the warming of the inspired air on its way to the lungs, but of filtering out of dust-particles. It has since been demonstrated[10] that they act in like manner toward bacteria. Indeed, *a priori*, the waving cilia of the epithelium and the residual pulmonary air are anatomical phenomena which constrain us to believe that the bacillus of pulmonary tubercle and the dust of pulmonary anthracosis do not reach the periphery of the respiratory system of the lungs by the air-channels themselves. They must be carried thither by other agencies. We know of none except the blood-current and the lymph-stream. We find them in the lymph-channels and we have many reasons for believing they are thus carried, but the difficulty of submitting the blood-current and its channels to microscopic examination in this respect, the absence of any such blood-filters as the lymph has in its nodes, preclude us from denying or asserting that the blood-vessels also carry the germs from the surface. But perhaps this is not a very important point in the consideration of the subject. The lymph-channels do carry material absorbed from the surface whether the blood-vessels are also carriers or not. The interesting, and I venture to predict significant, phenomenon connected with the subject of infection is that apparently the mucous membranes absorb, the lymphoid material harbors, and the lymph-channels carry the tubercle bacillus and yet are themselves relatively immune to its morbific influences as compared to the walls of the bronchioles and air-vesicles. We must remember, however, that this is not so much the case with the cervical and bronchial glands, though many observers believe that they are as a rule only secondary points of development, the primary nidus being in the lungs; but the mucous membranes of the upper air-passages not only receive the primary deposit of the infecting agent, but they are subsequently, in case of the establishment of a pulmonary nidus, washed by the virulent cultures thrown off from the distant point of development, without themselves, as I have just said, in the majority of cases, presenting evidences of morbid action.*

Now, if in the air-tract we try to arrange the anatomical localities in the order of the frequency of development of tuberculous disease, we find it proceeds pretty regularly from the walls of the bronchioles and air-vesicles to the nose, the larynx perhaps being more frequently involved than the trachea or larger bronchi on account of its greater mobility and the complexity of its gross anatomy.[1]

The lungs, the larynx, the oro- and nasopharynx, the nose, this being the order of frequency of the site of tuberculous disease, and, in all but an insignificant number, the lungs being the primary seat of the efflorescence of the disease and the other localities merely incidents in the total history, when it occurs to us that this is the inverse order of frequency in the primary contact of the tubercle bacillus in the air-current, there seems no escaping the conclusion that the tissues themselves possess powers of resistance in certain localities which they do not have in others. Now, what does this possibly mean? We must keep in mind what the bacteriologists teach us as to the enormous variations in the virulence of the bacillus itself. We must remember the individual as well as the generic variation of both bacteria and their hosts in the general scheme of the bacterial etiology of disease. I am not here concerned with the bacillus nor with its relation to general systemic processes in disease, but with the phenomena of its relation to the nose and throat. The same phenomena are to be observed elsewhere. It adds nothing to our actual knowledge to theorize, but it adds greatly to the efficiency of our intelligence to do so, and it is an immense help to us in subsequent investigations and experiments. Shall we say that the tubercle bacillus only acquires virulence as to its host in its passage from the throat along the pathways of infection to its point of development? This seems fantastic. Shall we imagine that its greater frequency upon or adjacent to the mucous surfaces of the nose and throat has induced a sort of local inoculative immunity? Or shall we say that this greater exposure has in the process of evolution of the animal organism produced a graded *local* immunity which is inherited? Then comes the familiar, but the uncomfortable thought, does not evolution partly mean the weeding out of susceptible strains generally, by exposing them to the ravages of disease? And if our somewhat arrogant hygienists really succeed in decreasing the number of exposures by their onslaughts on the bacillus, will not the susceptible strain in the human race increase and the net result be the same, unless the bacillus is totally annihilated? It is thus easily seen how quickly and necessarily one drifts out of special channels into broader, if one but follows one's argument to its inevitable conclusion of interrogation.

I am very anxious that the etiological problem

*In the early statistics of Louis (Recherches Anatamo Pathologiques sur la Phthisie, 1825) of the cases in which the air tube was examined post-mortem and declared free from phthisis, the epiglottis was involved 18 times, the larynx 72, and the trachea 11 times, but he does not state distinctly the relation of the involvement of any or all parts of the tube to the whole number of pulmonary cases. His statistics are however suitable for use today by the non-existence of syphilis and other causes of the air tube, and the same may be said of Trousseau and Belloc (Traité de la phthisie pulmonaire, 1840). Hence they are only valuable as showing the great high percentage of tuberculosis of the larynx and trachea in phthisis. It must be remembered that all these and many other statistics are from the extreme stable material of pulmonary phthisis, and include the ravages of the last stages of the disease in which not infrequently the whole trachea and bronchi break down and ulcerate. At a time when pulmonary phthisis was much less frequent and in its first and second and third stages often passed unnoticed, Louis's statistics of the point of origin of the pulmonary lesions, and the order of their extension, agree remarkably well with the investigations of the present day.

[1] I wish to explain that I am not now considering latent tuberculosis of the tonsils and lymph-nodes, which, if it is to be called a disease at all, is to be considered a disease thoroughly repressed by the resisting forces of nature, and therefore as contributing to the striking phenomena to which I am alluding. Clinical tuberculosis is one revealed by the symptoms and not exclusively by the microscopic study of the tissues. I should also say that Trousseau and Belloc long ago stated that the trachea was more frequently affected than the larynx, but Andral about the same time made a contrary observation (Clinique Medicale, 1834, T. 4, p. 182) and I do not now recall any observations of late years which throws any more light on this particular point, for the advent of laryngoscopy by revealing the laryngeal lesion clearly and the tracheal lesion obscurely, or not at all, has confused rather than elucidated this point, and is especially open to error from a clinical standpoint because the symptoms in tracheal ulceration are comparatively mild and apt to escape notice in the presence of other lesions.

with which I have been concerned should be stated not in its usual form, "What is the cause of laryngeal tuberculosis?" but rather what is the cause of the comparative immunity of the upper air-passages? We should always be reminded of this when the fact is brought to our attention that primary disease of the upper air-passages is so rare that its very occurrence has been doubted. So far as the bacillus is concerned, he seems to be powerless until he has been baptized in the lungs and born again, or until he has there on his vantage-ground sapped the forces of general systemic resistance. I hope I have been able to present this phenomenon in its proper vivid light, as a puzzling problem of vital importance.

I see upon referring to the program that I am expected to say something of the pathology, but it seems to me I may safely neglect this, at least so far as concerns its histology. The pathology of tubercle in its microscopic features is the same everywhere and it has often been said that Virchow many years ago selected the larynx as the place where the common type of the lesion can best be studied. Although Trousseau and Belloc failed to note tubercle in the larynx in their cases of ulceration with pulmonary phthisis, considering the ulceration of a simple inflammatory nature, Broussais as early as 1806 had observed it.[11] Since the development of laryngoscopy the gross pathology is better considered under the heading of diagnosis.

In the consideration of the remaining part of my subject which I shall have time to touch upon, I shall confine myself exclusively to that lesion which is at once the most common in occurrence, the most distressing to witness, and the most difficult to treat, namely, laryngeal tuberculosis.

In speaking of the diagnosis there are three points upon which I wish to dwell with especial emphasis, (1) the diagnosis of incipient laryngeal tuberculosis; (2) the differential diagnosis of tuberculous from syphilitic laryngitis, and these include the (3) salient point, namely, the microscopic examination of the sputum.

1. When the laryngologist is aware that his patient is suffering from pulmonary phthisis and has come to him for hoarseness, he is naturally on the alert for the detection of the involvement of the larynx in the disease. He is still more so if the patient also complains of pain. Upon looking into the larynx and finding it much reddened, but without any local hyperplasia or infiltration, he may be pretty confident that the laryngeal symptoms and appearances are dependent upon the cough and perhaps upon the general systemic debility. This frequently, even postmortem, deceived the early observers. The phthisical patient may come with much less-marked symptoms than in this secondary catarrhal laryngitis, and yet have in his larynx the unmistakable evidence of tuberculous disease in its incipiency. Inspection reveals in addition to the pale larynx and velum palati, so suggestive of pulmonary phthisis, one which is congested only in spots. There is a heaping-up of proliferated epithelium on the posterior wall, the pachydermia laryngis. But these are appearances which are merely suggestive, not confirmatory of tuberculous laryngitis. We must have some local infiltration or ulceration to render this suggestiveness a probability, a certainty it cannot become until we have exluded syphilis and found the bacillus of tubercle.

The description of the laryngoscopic appearances of tuberculous infiltration and ulceration of the larynx can best be left to the text-books and the routine descriptions, though I often question the utility of surrendering space even there to them. I doubt if any one ever made a diagnosis of a tuberculous or syphilitic ulcer from his experience with didactic descriptions alone. Neither shall I say anything of the symptomatology.

I have been supposing that the laryngoscopist was informed from the symptoms, or history, or physical examination, as to the condition of the lungs. The case is very different when there is no suspicion of pulmonary involvement. I am familiar with the eloquent and impressive phases with which many writers delineate the accuracy of diagnostic acumen possible in laryngoscopy which recognizes at a glance without collateral evidence the existence of pulmonary phthisis. I have no hesitation in disclaiming any personal skill of this kind. The cough, the emaciation, the pallor, the patient's apprehensions, and his history, put me on my guard. Laryngoscopy strengthens or weakens my suspicions, but I confess I have to go further for a diagnosis. Physical evidences of pulmonary involvement with the laryngoscopic evidence will form a probable diagnosis, but the presence of the tubercle bacillus must confirm it. Before proceeding further in the question of differential diagnosis we must consider the second point of interest.

2. Syphilis of the larynx is not a common occurrence in my experience, syphilis of the lungs is not unknown to it. When the two are combined they present a clinical picture which is sure to deceive the unwary diagnostician who lays too great a stress upon the element in differential diagnosis of most frequent occurrence. What makes this mistake more distressing to the conscientious practitioner is the fact that laryngeal syphilis is usually an easily curable disease, but with the same treatment as that used in laryngeal tuberculosis it is almost as fatal as the latter. The observers who first studied these laryngeal affections in the early part of this century were continually confounding them and they were both called laryngeal phthisis. In no other affection does such great importance attach to the diagnosis. It is usually a matter of life or death to the syphilitic patient. The comparative futility of treatment makes it of less importance to the tuberculous patient.

With a history of syphilis and scar-tissue in the pharynx or on the epiglottis, with the peculiar sharp-cut serpiginous ulceration characteristic of syphilis of the mucous membranes, the diagnosis is easily made, but local appearances in syphilitic disease, while frequently different from other forms of ulceration and we thus speak of characteristic

conditions, may so exactly resemble those of a tuberculous nature that they are indistinguishable from it. The promptness and suddenness with which laryngeal stenosis may supervene in syphilis is a differential diagnostic point which is frequently neglected. Tuberculous laryngitis is usually not accompanied by dangerous dyspnea. Syphilitic laryngitis usually is.

Fortunately there is usually no difficulty in clearing up the diagnosis, if the observer is on his guard. "Always think of syphilis and keep on thinking of it," irrespective of long personal acquaintance with the patient and his family, disregarding any church-going proclivities and notwithstanding his solemn asseveration. All the patients whom I have seen die from this mistake on the part of their medical attendants and one who was saved by previous experiences, were innocent women, who so far as could be learned from the history, had apparently unknowingly acquired the disease.

3. The greatest practical benefit which is at present clearly demonstrable we have derived from the discovery of Koch is the diagnostic value of the tubercle bacillus. In incipient cases of pulmonary involvement the bacillus is frequently absent from the sputum or there is no sputum as we all know; but where there is a laryngeal lesion resembling syphilis the primary pulmonary lesion has usually advanced so far that it is very exceptional, indeed, to be unable, on careful repeated examination, to find the tubercle bacillus.

Therefore in these cases of laryngeal disease it is of the utmost importance, both in the incipient stage and in the ulcerative stage when there is danger of confounding it with syphilis, that the sputum analysis should not be neglected. If the bacillus is not found iodide of potash and mercury should be given until the case is cured or the diagnosis is clear. I have many times urged caution in this regard and I do not hesitate here to reiterate a warning which may occasionally save a life.

Treatment of tuberculosis of the larynx, still more even than treatment of pulmonary tuberculosis, is a most vivid reminder of the impotency of man in the face of the destructive forces of Nature. Our helplessness lays us open to the bitter satire of that gifted ancient charlatan, Aesclepiades, who pronounced the therapeutics of Hippocrates to be the contemplation of death. It is doubtless true that occasionally a patient recovers under various methods of treatment. They also recover in exceptional instances without local treatment. There is a retrogression of the tuberculous infiltration and a cicatrization of its ulcers. This occurs under the local application of many medicinal agents, lactic acid and creosote being the most frequently employed in the last decade, iodoform and various balsams being perhaps as frequently used during the preceding ten years. Quite as extravagant and enthusiastic claims have been urged for one drug as another. So far as the impartial observer may judge the results have been approximately the same. I am under the impression that in laryngeal, as in pulmonary tuberculosis, climatic change is the most effective agent in the cure of the disease. Unfortunately such a very large proportion of these cases are inevitably doomed that it is cruelty to send them away from home to die, while in quite as large a number of cases climatic change for financial reasons is impracticable. It is not a part of the subject allotted to me to enter into the discussion of climate in the treatment of phthisis. Suffice it to say that the ideal treatment of laryngeal phthisis would be one in which the local measures could be judicially and skilfully carried out during the continuance of climatic treatment.

A few words must be said as to the surgical treatment of tuberculous infiltrations of the larynx, a procedure so popular with our German confreres. Again when we come to consider the results as to cure it is only a repetition of what has been said as to the application of drugs. A certain very small number recover under treatment. Whether more recover under this plan than under other methods or without treatment is a question which has never been satisfactorily answered, though frequently asked. Even the most enthusiastic advocates of the method admit that a large majority of the cases seen are unsuitable for operative treatment. From what I have said it will be clear that I am of the opinion that after an exhaustive search of the statistics, after an impartial weighing of the statements of numerous writers, after an extended clinical experience, the unbiased observer will come to the conclusion from the evidence thus studied, and not from that of a few selected cases, that the permanent radical cure of the local lesion of tuberculous laryngitis is not materially hastened by the various methods of treatment in any but an insignificant number of cases.

Now, I have been speaking of that part of the treatment of tuberculous laryngitis which is expected to end in its cure, and by that I mean the permanent cicatrization of the ulcers and the complete disappearance of infiltration from the larynx. When we discuss the palliation of the dreadful symptoms, we are dealing with another matter. Indeed, it not infrequently happens in tuberculous disease, and is characteristic of lupus for partial cicatrization of the ulcers or partial absorption of the infiltration to occur at one place and more extensive involvement to begin at another point and possibly in a locality where it cannot be seen, as in the ventricles, or where it ceases to produce pain, as below the cords or deep in the tissues. We therefore very much more frequently witness partial or temporary healing and even apparent cure than complete and convincing eradication of the disease. With this incomplete cure is a marked cessation of the distressing symptoms and a consequent increase in the euphemistic and hopeful mood of the patient. This brings me at once to one of the most important elements in the palliative treatment of the disease, the psychical one. It has always been recognized as a peculiarity, indeed, we may say as a symptom of phthisis, that the patient

is possessed, to the point almost of obsession, of belief in his continued improvement and ultimate recovery. No intelligence is too profound, no physical condition is too desperate, for the entertainment of this delusion, or of this assurance—a striking refutation of the influence of mind over disease and a striking illustration of a less mysterious phenomenon, the influence of disease on the mind. Now, it is the height of folly and it is the depth of cruelty to declare to this patient that nothing can be done for the cure of his laryngeal condition. It will bring about a depression, temporary, it is true, but productive of a marked injurious influence upon his general condition. In most cases we may evade technical falsehood by virtual deception, telling the patient much can be done in the way of treatment which may relieve his sufferings. Often he will not press his physician for more, for he, as Petrarch said in one of his Latin letters, "clings to every glimmer of hope and soothing the anguish of his soul with treacherous supports, ne forgets the most familiar of his own experiences." Any active local treatment, if it does not really aggravate the patients suffering, is pretty sure to produce grateful expressions of a belief in its efficacy and a lively hope of a successful issue. It is a fact that lactic acid and probably some other drugs will stimulate torpid granulations to a more florid and healthy appearance, frequently cause a marked diminution in the amount of secretion, more rarely bring about a decrease in the inflammatory swelling of the tissues, and even occasionally produce an evident cicatrization at the edge of the ulcers. I can testify from my own experience that even complete healing of a tuberculous ulcer may thus occur. More than ten years ago such a laryngeal condition healed in this way for several months while the patient was pregnant, but subsequently, I think after more than a year, the laryngeal trouble recurred with stenosis and in spite of an intubation which relieved the latter symptom, she rapidly succumbed to her pulmonary lesion. This, however, is with me an almost unique experience and I regarded the case at the time as cured. I cannot doubt as I look back on it now that for some reason, perhaps from the curetting which was also done, or possibly from systemic reasons, the tuberculous disease subsided and was held in abeyance. Less striking results than this are not infrequently attained and any diminution in the intensity of the morbid process causes marked amelioration of the distressing symptoms when aided by the psychological element just alluded to. Even when no apparent change in the lesion can be noted, the assurances of the patient are for a time often very gratifying if not, to the experienced observer, encouraging. The local application of iodoform, and especially of orthoform in the elegant prescription employed by Freudenthal, produces frequently a more marked influence by its continuous use upon the pain, but it has seemed to me that it has not so frequently produced a better local condition of the laryngeal ulceration. The intralaryngeal or intratracheal injection of oils impregnated with various volatile substances, especially menthol, frequently, for the time at least, ameliorate the pain and the cough. As for the opiates internally, their employment is often justifiable and indicated. The local application of cocaine is rarely of any value, as it does not exert much influence on inflamed tissue. Detergent sprays wash away the secretions and give relief until the latter gather again, the impression on the patient's mind being often more lasting.

Finally, in a patient without much fever, with considerable vital force yet remaining, with proper fortitude of mind, but especially with the docility which seems more common in the Teuton than in the American, the removal by cutting forceps and curette of granulations and infiltrated tissue, especially the surface vegetations covering ulcers and the infiltrated substance of the epiglottis, is often followed by the most happy results as to the relief from the tormenting dysphagia, and less frequently by cicatrization of the wound. The submucous injection of various medicaments, especially creosote and lactic acid, does not appeal to my understanding of pathological processes, but it has its advocates in the larynx as well as in the joints, who are just as positive and enthusiastic and as honest as the partisans of other procedures. Indeed, as to the *cure* of laryngeal tuberculosis by agencies at our disposal in the present stage of our knowledge, honest belief as to that seems to be largely a matter of individual temperament, but being a debatable field it affords an opportunity for much dishonest expression of sentiment which deserves only our contempt. Even the perfectly honest, but unduly exaggerated expression of opinion as to the results to be attained by any method of treatment and the uncritical narration of the histories of only favorable cases has been very misleading. This tempermental optimism, together with the barefaced charlatanry which suppresses what the reporter knows to be the whole truth, has unfortunately been a great detriment to the conscientious study of the treatment of this terrible disease. One cannot expect human nature will allow men to be constantly exhibiting to the world their own dismal failures as an offset to the reported brilliant successes of others. Yet it is only by the unflinching and conscientious adherence to what one believes to be the whole truth that we will stimulate that activity which may in the future find that cure for tuberculosis in man which we do not now possess.

NOTES ON THE INTERESTING CASES OF A MONTH'S DISPENSARY PRACTICE.[1]

By WILLIAM L. STOWELL, M.D.,
NEW YORK.

The object of a paper read before our Society I understand to be to present original observations and research or to promote discussion. Only the latter object can be served by these cases from the Demilt Dispensary, for they have no relation to each other, nor are they rare diseases.

Peripheral Neuritis.—Maggie B., aged thirty-one years, was a large-framed married woman, very obese. She came from the country a healthy young woman. Here she began the use of beer and liquors which increased her weight, but she lost in energy of mind and body. Four months ago she had so much pain in the limbs that she took to her bed. There was great weakness when walking, so that she had to be supported from both sides. The cutaneous reflexes were preserved, but seemed slow. The wrist-drop and foot-drop were incomplete. The appetite was poor and digestion imperfect. There was marked constipation most of the time.

Neuritis is classified as localized, multiple, acute polyneuritis, recurring and alcoholic. All these forms were readily eliminated except the last. The treatment ordered was iron, quinine, and strychnine, and no alcohol. Later she went to the hospital where she could have electricity and massage.

Universal Eczema.—Ellen St. J., married, forty-two years of age. For some weeks there had been an ulcer an inch in diameter on the right ankle. As it itched she bathed it freely with alum solution. After a vigorous bathing one night she found the itching extending up the leg and thigh. It later involved both legs and extended to the genitals and trunk. Next the face and neck were affected and, finally, the arms. The ears, eyes—in fact, all the face—were greatly swollen, red, moist and bullous. At this time she was treated for erysipelas. She came under my care as the face began to improve. Desquamation commenced in flakes, as it did over the body and limbs.

Treatment consisted of solution aluminium acetate externally, with rhubarb internally. The patient had menstruated irregularly for a few months, but was in as good general health as women usually are at the menopause. The diagnosis was not exactly certain. The first physician declared the disease erysipelas and gave up the case as he claimed he could not attend it and confinements. The tumefaction of the lips, eyes and ears may also be prominent in dermatitis exfoliativa. Itching is marked in both. The rapidity of extension and fine, bran like scales tend to strengthen the diagnosis of dermatitis. The case was entirely cured in six weeks.

Pneumonia.—Frank B., aged four years, had a catarrhal pneumonia with a temperature reaching 104° F. The usual temperature in bronchopneumonia I find lower than that in the croupous form. The case progressed well under an alkaline mixture of acetate of potash and niter without antipyretics. During convalescence a malt preparation with hypophosphates was given.

The second pneumonia case was in a child of three years. Here there was a fibrinous pneumonia of the left upper lobe. This child, although "a boarder" and poorly nourished, managed to recover thoroughly. When I was in the hospital as interne every case had stimulants and an oiled silk jacket. Neither of these patients, in fact none of my pneumonia patients, have either. For a time I had oiled silk jackets made and lined with lambs' wool instead of sheet-lint or cotton. Of late, without special reason, I do not order jackets.

Alcoholic stimulants I definitely eschew because when given in considerable quantity they cause stupor and greatly interfere with digestion, in both cases masking the symptoms of the disease out of proportion to the value received. There are many physicians and many different views as to the value of alcoholic stimulants, but it is very clearly seen, upon consulting recent works on therapeutics or practice, that the majority of authors recommend alcohol "cautiously," "with judgment," "in certain cases," and the like. The day of "alcohol by the pint" has passed. Tirard says in his recent work on treatment, "but the lavish employment of stimulants as a mere matter of routine is distinctly to be deprecated."

My treatment is a very simple alkaline mixture early, and strychnine late. Children bear both strychnine and nitroglycerin well in doses of $^1/_{500}$ or $^1/_{250}$ of a grain, according to age and degree of weakness. I order an occasional dose of Dover's powder at night or phenacatin, with $^1/_{30}$ grain of morphine. Digitalis, strophantus, and caffeine are much lauded and perhaps used. Tirard recommends small doses of chloral with a stimulant for restlessness. I believe that the outcry against coal-tar antipyretics is unnecessarily loud. Large doses in weak subjects do cause collapse. Likewise do aconite and veratrum viride if pushed too far or prescribed unwisely. For many years my favorite antipyretic, when one was needed, has been acetanalid in one- or two-grain doses for children and five-grain doses for adults. Suitable doses do not require alcohol to offset evil effects. Poultices of flaxseed relieve the pain and dyspnea of the croupous cases, but cannot wisely be continued much more than two days. A mustard and flour poultice gives as much local heat and is more suitable for catarrhal cases.

Typhoid Fever.—During the past four weeks there were four typhoid patients aged eighteen, eight, five and three years, respectively. This is in proper accord with the season, since 75 per cent. of the cases occur during the last four months of the year, hence the old name "autumnal fever." These cases were typical of the disease as it occurs in youth and childhood. The eight-year-old child had a temperature of 104.5° F. at the end of a week. She presented rose spots, dry, parched skin, feeble, compressible pulse, and marked apathy. The bowels were loose, but diarrhea was not severe. Her mother was in the hospital with

[1] Read before the Demilt Dispensary Society, October 19, 1900.

typhoid and I sent her there also, as there was no one to care for her at home. She made a good recovery.

The five- and the three-year-old children were brothers. The source of infection was not known. Each had spots and slight enlargement of the spleen. The three-year-old child had high temperature and stupor. He was bathed to reduce temperature and took no medicine except a simple cough mixture. When convalescence began he took elixir of iron, quinine and strychnine. The three-year-old child was dull and apathetic, but had no diarrhea. As he had a coated tongue and no appetite, I ordered the officinal rhubarb-and-soda mixture. In reality he took very little of it. A sample of blood from the older boy gave the Widal reaction promptly. The diagnosis was made independently of it, however.

I am still one who believes in clinical diagnosis and, though glad to have bacteriological confirmation, am not willing to have one bacteriological negative offset clinical evidences that are positive. When there was an epidemic of twenty-eight cases in the hospital the blood was always examined for Widal and generally the urine for the diazo-reaction. The reaction usually showed typhoid to be present, but the failure to substantiate the diagnosis weighed little.

The fourth patient, eight years of age, is still quite ill. She had the "characteristic semicadaverous, musty odor." During the diarrhea period she one day had about thirty stools. The spots on this patient were very few. Tympanites and stupor were both marked, the former not until the diarrhea was checked. This patient was given the antiseptic tablets of Woodbridge for two days with good result. How the $^1/_{960}$ grain of podophyllin acts is a mystery. Salol and bismuth in paregoric and mucilage formed the treatment part of the time.

Milk and liquid peptonoids formed the basis of food for each of these cases. I often allow ice cream and begin early to add custard, eggs, etc., to the dietary. None of these fever patients received any whiskey. To be sure, there is alcohol in the peptonoids, but in small quantities.

The prognosis is good in childhood, but when death does occur it is from about the same causes as in adults, *i. e.*, hemorrhage, pneumonia or exhaustion. Nursing is more important than drugging. Exact rules should be laid down as to prophylaxis. At present in the United States 27,000 patients are lost each year—a standing army wiped out. My share in this mortality has been 2.05 per cent. of my cases.

Chicken Skin Grafting.—According to Bianchi and Fiorani (*Gazz. degli Osped.*, Dec. 2d, 1900) chicken skin has been successfully used for human skin grafting. They report the case of a female patient 50 years of age suffering from gangrenous erysipelas. After the termination of the erysipelas a large granulating surface was left. Fourteen grafts were taken from the skin of the breast of the chicken. Only three failed to grow.

CLINICAL MEMORANDA.

A CASE OF ADIPOSIS DOLOROSA.

By ELLICE M. ALGER, M.D.
OF NEW YORK;
LECTURER ON DERMATOLOGY IN THE NEW YORK POLYCLINIC; PROFESSOR OF DERMATOLOGY IN THE UNIVERSITY OF VERMONT.

IN 1882 Dr. F. X. Dercum, of Philadelphia, published under the title "A Subcutaneous Dystrophy Resembling Myxedema," a description of a peculiar case observed by him, and a few years later he gave the appropriate name adiposis dolorosa to the disease, as best describing the symptoms characteristic of it. Very few cases have been observed, and as yet but little is known about the etiology of the disease, and there is a considerable difference of opinion as to what constitute the absolutely essential symptoms and what are merely incidental to the score of cases on record. This element of doubt must be my excuse for publishing a case which, while agreeing closely with the cases on record, has many points of divergence.

The disease has thus far been found to occur always in women, generally just past middle life, and almost invariably has been associated with some neurotic or alcoholic taint. It is characterized by the development, sometimes symmetrically, sometimes irregularly, of masses of fat, which are or have been painful, either spontaneously or on pressure. Sometimes the pains are like those of a neuritis and precede by some time the appearance of the fatty mass, and the mass itself is said to be usually softer than is simple adipose tissue. It imparts to the touch a sensation like that of a varicocele. These adipose masses vary in size, but in well-developed cases exceed very much the measures of those of my patient, and somtimes appear to vary in size with the presence or absence of paroxysms of neuritic pain, although they never at any time totally disappear. A peculiarity in the distribution of this adipose tissue is that in no case thus far recorded has it occurred on the hands or feet or face.

Certain nervous phenomena have been noted by various observers, such as diminished cutaneous sensibility, extending even to local cutaneous anesthesia. There is often a complaint of great muscular weakness, and in a few instances the reaction of degeneration has been elicited. Hematemesis, epistaxis and excessive menstruation have been so commonly found that they may be considered symptoms of the disease, while other signs, such as headache, impairment of mind, bronchitis and purpura are very likely only incidental. Painful swellings along nerve trunks have been observed frequently. The skin itself is usually unchanged, is soft and pliant, but often very dry, and sometimes contains more pigment than normal.

In Dr. Dercum's original case an examination of the eye revealed contraction of the field of vision for form and for color, and some of the other senses seemed somewhat blunted. In two of his cases, in which autopsies were obtained, the most striking pathological feature was the calca-

reous infiltration and induration of the thyroid gland with changes, as yet unstudied, in the structure of the nerve-tissues. He concludes that the disease is a connective tissue dystrophy, with a fatty metamorphosis, associated with symptoms indicating a possible neuritis.

According to the same observer, the differential diagnosis lies between acromegaly, myxedema, simple obesity and *lipomatosis perimuscularis circumscripta*. The first two affect the hands, feet and face markedly, and are not painful, while adiposis dolorosa has thus far not been observed in these regions, and has pain as a prominent feature. In the last two the fat is symmetrically distributed, especially about the face and neck, while there is entire absence of pain.

My patient came to consult me about a number of painful nodules and tumors scattered over her body, and gave the following history: She is of American birth and twenty-nine years old. Her mother is living, and is very stout; her father is dead, but she does not know the cause of his death; she has two sisters, one of whom weighs over 200 pounds, and although both have been married some time, neither has been pregnant. There is nothing to indicate that the sister has adiposis dolorosa. There is no history of any hereditary disease in the family. The patient was very healthy as a child, but had measles and scarlatina; she began to menstruate at eleven years of age, and at sixteen married a man of thirty, who had several children by a previous wife, but the patient has never been pregnant. She menstruates profusely, sometimes as often as every two weeks, and has been treated for some uterine disorder, judging from her description, endometritis, with ulceration of the cervix, for which she was curetted. She now has not any symptoms indicating uterine disease excepting profuse menstruation and sterility.

The patient has a good appetite, eats heartily, is constipated, and not living very happily at home; she shows a pronounced neurasthenic tendency, and at times is probably hysterical. Eight years ago she weighed 130 pounds, and had a good figure. At that time she noticed a small lump on the inside of the left thigh, half way up from the knee. It was subcutaneous, and gradually grew larger, until at the present time it is two inches in diameter, and is very painful on pressure, but not otherwise. This swelling is superficial and rounded, is covered by normal skin, shows no signs of inflammation, and feels like a fatty tumor. During the last year similar bodies have appeared, as follows: One on the right arm over the triceps muscle, and one on the left arm, near the insertion of the biceps. There are none on the face or neck or upper part of body, but several small ones have lately appeared about the forearms. There are five or six in a chain on the outside of the right thigh, and several more on the left buttock, and one has lately made its appearance near the inner aspect of the right knee. During the past three years the patient has been getting very stout, the flesh not being distributed evenly, for it does not show on the face or forearms or lower limbs. There are great rolls of fat about the breast and back and buttocks and upon the upper arms and thighs, but there is not any pain in these rolls unless some of the smaller fatty tumors already alluded to are present.

The patient when first seen weighed 206 pounds, and her measurements were as follows: Height, 5½ feet; a No. 6½ glove and a No. 5 shoe are worn easily; ankle, 8½ inches in circumference; calf, 14½; thigh, 27½; hips, 43½; waist, 28; bust, 42½; upper arm, 14¾; lower arm, 10; collar, 14½. The appearance of these fatty tumors, she says, is preceded for several days by an aching sensation, and at times the limbs are cold, while at other times they burn and throb. She nearly always feels tired and weak, and says her skin is at times numb; at present sensation seems normal. Her thyroid gland cannot be made out. She has a good face, not at all fat, an intelligent expression, and aside from her constant disposition to melancholy shows no decided mental peculiarity. She has a good deal of dark hair, which shows no tendency to fall, and her skin was at the beginning very smooth, soft, of a good color, and performed its functions normally. I cannot elicit any history or symptoms of syphilis, except a vague and constant pain in the bones, which, however, does not seem to be periosteal in character. With the idea of relieving this she was given dram doses of iodide of potassium three times daily by another physician, but without any effect.

Bearing in mind the fact that in the cases which have gone to autopsy, the thyroid has been found to have undergone calcareous degeneration, the patient was put on gradually-increasing doses of thyroid extract, reaching as high as thirty-five grains a day. The results were that her weight was slightly reduced, and with it some of her measurements, but treatment seemed to have absolutely no effect on the peculiar tumors, either with reference to their size or tenderness, although the patient declared that she felt much lighter and stronger. The improvement, however, was not marked enough to cause her to persevere in the treatment. Being an outdoor patient, and very irregular in her attendance, my records are very incomplete as to the condition of the urine and blood, and permission to excise portions of tumors or take photographs was repeatedly refused, and the patient finally left the clinic. Under thyroid medication the skin had become notably less soft, and showed a brownish pigmentation.

117 East Twenty-sixth street.

Placental Transmission of Tuberculosis.—This vexed question is answered by G. d'Arrigo (*Centralb. f. Bacteriologie*, Dec. 8, 1900), as follows: Inheritance can possibly take place in three ways: (1) By impregnation of ovum by bacilli containing spermatozoa; (2) by infection in an ovum which is from a tuberculous ovary; (3) by the passage of the bacillus through the placenta. He has never found the necessary conditions for the first two, but has obtained experimental proof of the last.

LIGATION OF THE INTERNAL JUGULAR VEIN FOLLOWED BY THROMBOSIS OF THE LATERAL AND SIGMOID SINUSES.

BY CHARLES G. LEVISON, M.D.,
OF SAN FRANCISCO, CAL.;

CHIEF OF SURGICAL CLINIC, UNIVERSITY OF CALIFORNIA; ASSOCIATE PROFESSOR OF SURGERY, POST-GRADUATE DEPARTMENT, UNIVERSITY OF CALIFORNIA; CONSULTING SURGEON TO THE CALIFORNIA EYE AND EAR HOSPITAL.

THIS ligation is not infrequently performed, though the subject, strange to say, has been much neglected in medical literature. Removal of malignant growths of the neck is the usual indication for the ligation of the internal jugular, which, when ligated, materially facilitates the removal of the growth. The operation here referred to is not the one that has been performed so frequently and about which so much has been written during the past few years, in connection with thrombosis of the lateral sinus in middle-ear disease. Here the jugular has been occluded by a thrombus, and is easily tied as the vessel is devoid of blood.

The ligation of the full jugular has always been considered an operation which was followed by a high mortality, this having been confirmed by the earlier statistics of Braun, who collected fifty-one cases, with a mortality of 12 per cent., all due to secondary hemorrhage. Even at this time there is a large mortality following the operation. Rohrbach has collected seventy-seven cases of ligation of the internal jugular during the removal of malignant growths of the neck, with thirteen deaths, although he claims that none of these were the direct result of the operation. In the series of ninety-one cases collected by him only one death was directly attributed to the operation. In thirteen cases of ligation for wounds of the vein reported by him there were no deaths. In all these ninety-one cases collected secondary hemorrhage did not supervene in a single case.

It is now accepted as a fact that secondary hemorrhage is due to an infection, a factor which can be practically excluded by our modern methods. This is confirmed by Rohrbach's statistics.

The internal jugular is frequently wounded during the enucleation of glands and growths of the neck, necessitating a lateral ligation or suture. Braun has collected thirteen cases of lateral ligature, with a mortality of three; these statistics clearly demonstrating that the repair of the vessel-wall is accompanied by a far greater mortality than the actual ligation, and that the lateral suture is more fatal than the lateral ligature.

The following case was recently operated on in my service at the City and County Hospital. The patient, a man aged fifty years, with no luetic history, no hereditary tendency, entered the hospital to be operated on for a tumor, the size of an infant's head, which extended above to the jaw and almost to the medium line. It was firmly fixed to the tissues beneath. The diagnosis was carcinoma. The urine contained considerable albumin and casts, but the kidneys were secreting a normal amount of urine. The arteries were atheromatous. The operation was carried out under chloroform narcosis, and the base of the tumor quickly exposed. The jugular was found involved to such an extent that its removal was decided upon. The vein was tied one inch above the subclavian, and the distal end also ligated, about two inches of the vein, together with the growth, being removed. There was no reaction, no circulatory disturbance, no change in the size of the pupil. The patient reacted perfectly from the effect of the operation. The temperature and pulse were normal and the wound quite dry. At the end of the fifth day the patient became sleepy, slightly delirious and snoring, evacuating urine in bed. Temperature, normal; pulse 100° F.; respiration, 30 and stertorous. The pupils were moderately dilated, reacting to light. The kidneys were excreting profusely. Wound appeared normal; primary union. The diagnosis of the extension of the clot to the brain was made on account of the absence of paralytic symptoms, the gradual development of the coma (excluding uremia on account of the free flow of urine), and the stertor indicating some brain pressure. All of this subsequent to a ligation of this nature made the diagnosis probable. The patient died in coma on the sixth day.

The following is the report of the autopsy:

The wound of the neck was quite healed, the tissues presenting no evidence of suppuration or infection. The sternum and clavicle were removed and the vessels inspected in position. The peripheral end of the vein was obliterated, quite collapsed and devoid of blood, the silk ligature being intact and buried in the tissues. The distal end was found with some difficulty, as this end was deeply buried in tissues, already in full process of repair; the ligature on this end was also found intact. The distal end was distended by a firm clot. The brain was removed and the base of the skull exposed, when it was immediately recognized that the sinus on the operated side was distended with blood. Upon opening the lateral sinus down to the jugular foramen, an organized clot, continuous with the clot in the jugular, was discovered. The sinus on the opposite side and the longitudinal sinus contained only fluid venous blood. The arteries of the brain were atheromatous. There were no gross brain lesions. The kidneys presented the lesion of chronic parenchymatous nephritis. That this complication subsequent to ligation of the internal jugular is of infrequent occurrence is easily shown by reference to Rohrbach's statistics.

In this case infection was practically excluded for the thrombus was in full process of organization, as can be readily seen by the microscopic section prepared by Dr. Asch, of the City and County Hospital, to whom I here extend my sincere thanks.

The indications laid down by Rohrbach for the ligation of the internal jugular are as follows:

1. Hemorrhage due to a laceration or erosion—here the lateral ligature or suture has its place.
2. Tumors involving the vein.
3. Periadenitis due to tuberculous lymphomata closely adherent and inseparable from the vein.
4. Aneurismal varices.
5. Pyemic otitis, complicated by thrombosis of the lateral sinus.

606 Sutter Street.

MEDICAL PROGRESS.

Localization of Naming Center.—The cortical centers of several of our special senses have already been very definitely localized and by thoroughly studying clear cut cases showing, during life, the loss of some particular function of speech or hearing all the brain centers undoubtedly will soon be fully and definitely made out. G. M. HAMMOND (*Med. Rec.*, Dec. 29, 1900) reports two cases which were fully studied and the lesion localized later, but the findings do not entirely correspond with previous theories. One man was struck in the left side of head, fracturing the skull, and when he recovered consciousness had almost complete anomia, or loss of power to name objects. There was no motor aphasia, no word-blindness. On operating, a subdural hemorrhage was found along the superior temporal convolution. There was a rupture of the cortex at the junction of the middle and posterior thirds of the gyrus. One year later there was a very slight word-deafness which had been present from the first, but his anomia had entirely disappeared. The second case was one of softening of the middle third of second temporal convolution, secondary to thrombosis. There were no motor paralyses and no disturbances in sensation. There was no motor aphasia and the special senses were normal. He was completely word-deaf, word-blind and agraphic, leading to a diagnosis of the lesion, being situated in the superior temporal and angular gyri. The author, therefore, believes that word-blindness and deafness do not always imply that the lesion is situated in the higher visual or auditory centers, but that a lesion of any part of the speech area may so disorder the complex mechanism of the associated speech centers that any form of sensory aphasia may result.

Medullary Narcosis.—A further addition to the literature of medullary narcosis is given by H. VULLIET (*Therap. Monatschft.*, Dec., 1900). In operations below Poupart's ligament, including the genital organs, the patients invariably complained of numbness and formication in the feet after 1 to 3 minutes; in 4-6 minutes anesthesia in the lower extremities had set in, and in 6-8 minutes this had reached up to a line somewhere between the umbilicus and the bimammillary space. After the lapse of ½ hour the sensibility of arms, shoulder and thorax was much diminished. Certain interesting cases are quoted, thus in one patient the entire body became analgesic, another had lost thermic sensibility. After 1½-3 hours sensation to pain returned from above downward, and in not a few there was ataxia in the legs. Operations on the sexual organs seemed to be especially adapted to this form of narcosis. In hernia and appendicitis operations the method was less uniformly successful. For the neck and upper extremity it proved entirely inadequate. The usual dose employed was between 15 and 20 milligrams. Of after-effects, nausea and vomiting rarely disturbed the patient. Many, however, complained bitterly of headache, which lasted in some cases 2 to 3 days. Collapse symptoms were never found.

Gonorrheal Endocarditis.—A case of chronic malignant endocarditis, due to the gonococcus is analyzed by G. W. MC CASKEY (*Med. Rec.*, Dec. 29, 1900) showing also the findings at autopsy of a valvular lesion difficult to diagnose during life. A severe chill following self-catheterization on account of an old gonorrheal stricture brought the first notice to the case. Six weeks later the patient began to have general malaise, afternoon temperature, and progressive loss of flesh and strength. He had recovered from a severe attack of typhoid one year previously. The left ventricle was markedly hypertrophied, and a systolic and diastolic bruit were present over the second left interspace. It was also heard in the interscapular region behind. Later a severe hemiplegic attack occurred from an embolus, and numerous purpuric spots appeared before death. The aortic valves were thickened, distorted, roughened, and covered with vegetations. The mitral valves were somewhat insufficient, largely due to the dilatation of the left ventricle. The gonococcus was found upon the valves. The case seemed interesting also on account of the presence of the murmurs on the left side, due to lesions of the aortic orifice.

Suprarenal Extract in Middle Ear.—L. S. SOMERS (*Therapeutic Gazette*, Dec. 15, 1900) says that the aqueous extract of the suprarenal gland has a wide field in reducing congestion in all acute inflammations of the tympanic membrane and in all conditions of the external canal with presence of granulation tissue. It is necessary, however, to combine the solution with some antiseptic, since decomposition with subsequent septic infection is especially liable to follow in the aural canal; the addition of carbolic acid and eucaine has been found serviceable. In acute inflammation of the drum, with or without involvement of the tympanum, the instillation of from five to ten drops of the solution previously warmed will give temporary relief, and if this is repeated the affection can frequently be aborted in its early stages. Another advantage lies in the fact that, through the hemostatic action of the solution, incisions can be made without loss of blood.

Oral Sepsis.—Great stress is laid upon the importance of recognizing septic conditions of the upper part of the digestive tract by W. HUNTER (*Practitioner*, Dec., 1900), who believes that besides the local effects of gingivitis, stomatitis, necrosis, alveolar abscesses, pharyngitis, tonsillitis, etc., which are sufficient to cause much disturbance, there is a still more important influence exerted upon the stomach and the whole constitution. Dental disease is frequently the cause of indigestion in consequence of being a

gastric infection. The continuous swallowing of mouthfuls of pus organisms is not tolerated by the stomach mucosa, but besides any actual general infection there are those constitutional effects due to septic absorption, which the author believes quite common. The usual manifestations are the dirty ashen-gray look and general languor, irritability and feelings of intense depression which frequently occur without any local symptoms. Three cases of neuritis are also reported, simulating the condition which sometimes occurs in pernicious anemia, but which are given to illustrate how a toxic neuritis can be caused by the prolonged neglect of an intense condition of oral sepsis. The treatment should consist of direct application of strong antiseptic solutions to the diseased tooth or root and for a mouth wash he recommends a teaspoonful of carbolic, 1 to 20 or 1 to 40, in half a tumbler of water. All diseased stumps, roots or diseased areas must be energetically and thoroughly cleansed.

Ophthalmia Neonatorum.—As generally applied, the term ophthalmia neonatorum includes all of those cases of mucopurulent or purulent discharge from the eyes that presents itself during the first two or four weeks of the life of the child, and the general inference is that the infectious material enters the conjunctival sacs during or immediately after the birth of the child. JOHN E. WEEKS (*Amer. Gyn. and Obstet. Jour.*, Nov., 1900) says this impression should be slightly modified when one recognizes the fact that infection sometimes occurs antepartum, and that in those cases which develop later than three days after birth, the infection is almost always from a source other than the genitals of the mother; also that there may be a purulent secretion present in the conjunctival sac during the first month of life due, not to inflammation of the conjunctiva, but to an inflammation of the tear-sac dependent on an impervious lacrimal canal. The writer says that the gonococcus of Neisser is almost invariably the cause of this disease when the discharge appears before the end of the fourth day after birth. In the way of prophylaxis, a 1-1000 solution of corrosive sublimate, or a 2-per-cent. solution of nitrate of silver, instilled into each eye at the time of the first bath has given the best results. Weeks discusses the treatment of this inflammation after reviewing briefly the conditions obtaining in the eyes at this period. He describes the treatment under four headings, as follows: (1) Mechanical. The conjunctival sac should be cleansed very frequently with a 3-per-cent. solution of boric acid, or a sterile normal salt solution, or a 1-15,000 to 1-20,000 solution of corrosive sublimate. The solution should be warm or tepid. (2) The conditions for the development of the micro-organisms should be made as unfavorable as possible by reducing the temperature of the conjunctiva by cold applications, made continuously from one to four hours at a time, repeated three times daily. Pledgets of linen or cotton moistened and laid on a cake of ice may be employed, and should be changed every one or two minutes, as soon as warm. This treatment should cease when the swelling of the lids disappears. (3) The micro-organism should be destroyed as far as possible by the application of a germicide. For this purpose nitrate of silver, 0.5 to 2 per cent., bichloride of mercury, 1-5,000, protargal, 20 to 40 per cent., formalin, 1-3,000, are the best agents. The writer prefers 1-per-cent. solution of nitrate of silver applied to the entire surface of the conjunctiva once a day until the discharge from the conjunctiva ceases. (4) Constitutional treatment, which should be directed to the general improvement of the child's condition. The writer says that ophthalmia neonatorum treated by this method seldom results in impaired vision.

Inhalations in Pulmonary Diseases.—The success he obtained in treating pneumonia by inhalations of oxygen passed through boiling water, in which had been placed one dram of a mixture of creosote, oil of turpentine and compound tincture of benzoinum, has lead CLEMENT A. PENROSE (*Johns Hopkins Hospital Bull.*, Nov., 1900) to give the method a trial in other pulmonary diseases. His experience with this method in pneumonia proved definitely that (1) oxygen being heated and mixed with steam was more readily absorbed, less drying of throat and tongue, and more agreeable to the patient; (2) passed through a heated inhalation mixture like the above, it certainly had a marked antiseptic effect on the mouth and tongue, as shown by the pearance of these parts; (3) the pleasant odor of the inhalation mixture gave something tangible for the patients to breathe, who therefore made greater efforts to inhale the oxygen. Either oxygen, or compressed air, or simply steam alone, or a combination of these agents, was used in a number of cases varying from simple coryzas, various catarrhal affections of the pharynx and nasopharynx, grip, acute and chronic bronchitis, to pulmonary tuberculosis, with astonishing results. In some cases no internal medication was employed with results, when the inhalations were used early, about as good as when it was. A very few inhalations were sufficient to terminate quite severe cases of grip. The writer recommends, when a cylinder of oxygen can not be afforded, the "Benzoinal Inhaler" or the "Hynson and Westcott Inhaler." At the start he uses the following formula: R Creosote (Beechwood), Olei Terebinthinæ, aa drams 4, Tr. Benzoini Co., ounces 3. Of this mixture one dram is placed in a pint of hot water. As the patient becomes accustomed to the fumes, more and more of the creosote and oil of turpentine is gradually added until the mixture consists of equal parts of the three ingredients. The inhalations, to be effective, should be systematic and of from ten to fifteen minutes' duration each. The above inhalation mixture should be combined with steam alone, with steam and oxygen, or with steam at home and

with steam and oxygen at the office. The writer reports in detail three cases illustrating the beneficial results of regular inhalations of each of the above combinations.

Hyperidrosis of Axilla.—After testing various local and constitutional treatment for the above distressing skin lesion, L. KOLIPINSKI (*N. Y. Med. Jour.*, Dec. 29, 1900) has made use of a rather radical, but apparently successful method of dealing with this condition. The idea is to convert patches of skin with their hypersecreting glands into scar tissue and with this end in view he shaves and sterilizes the axilla and, without any anesthetic, thoroughly uses the thermocautery, turning one-half or more of the superficies of the axilla into burns of the second and third degrees. It is said that the pain is not severe. A dry bismuth or zinc-oxide dressing is applied and the patient is able to resume his work in a few days.

Bronchopneumonia in Infants.—A recent paper by ROSENTHAL (*Thèse de Paris*, 1900) contains some interesting conclusions based on a study of 23 cases of bronchopneumonia in infants. They are as follows: Bronchopneumonia results from descending respiratory infections by non-specific bacteria, pathogenic or accidentally pathogenic ones. The infection is extremely contagious in infants. Out of 19 cases of infantile bronchopneumonia, 15 were induced by Pfeiffer's bacillus, pure in 2 cases (1 benign, 1 fatal), associated in the other 13 cases with either the pneumococcus, streptococcus, diplostreptococcus, and enterococcus. In several cases the author found the enterococcus of Thiercelin (bronchopneumonia of intestinal origin). Rosenthal agrees with Marfan that the cachexia of sucklings is primarily gastro-intestinal in origin, later becoming pulmonary in character. The terminal bronchopneumonia progresses in an insidious fashion, the fatal ending occurs when the intestinal symptoms have disappeared. Fever is very slight, and the dyspnea scarcely appreciable.

Hypertrophy of the Thymus in Leucemia.—A contribution to the interesting and unusual feature of leucemia has recently been made by MOIZARD and LEVASTI (*Archives des Médecine des Enfants*, Dec., 1900). A review of the literature of leucemia shows that hypertrophy of the thymus is rarely mentioned as a complication or accompaniment of the disease. The first report of this condition dates back to 1871 when Cuvrim described before the Congress of Medicine held at Frankfort that year the occurrence of an enormously hypertrophied thymus in a child, five years of age, suffering from leucemia. Since the further contributions have been made by Krause, Cahen, Fabre, Lubomirski and Grawitz. A few cases of enlargement of the thymus have also been described in Hodgkin's disease by Bennett, Murchinson, Eberth and Birch-Hirschfeld. The patient observed by the writers was a girl, five years of age, who was brought into the hospital after having been sick but a few weeks. When admitted there was considerable edema about the parotid, submaxilliary and palpebral regions. The lips and extremities were cyanosed; respiration was hurried and laborious. The tonsils were large and the gums swollen. The lymph-nodes were much enlarged; liver and spleen were similarly augmented in size. The blood-count showed the presence of 1,252,400 reds, and 54,250 whites. The child died of asphyxia. The autopsy findings confirmed the clinical diagnosis. The thymus was further found to be much enlarged (8 mm. x 6 cm. x 8 cm); weight 111 grams. The intrathoracic pressure was found to be largely due to the encroachment by the enlarged thymus. The microscopic features of the thymus have considerable interest; the whole organ was transformed into tissue resembling that of an ordinary lymph-node, with a complete disappearance of Hassal's corpuscles.

Leucocytes in Acute Rheumatism.—ACHARD and LOEPER (*Comptes Rendus de la Société de Biol.*, Dec. 7, 1900) have completed a study of the leucocytes count in acute rheumatic fever. In the fourteen cases studied, they constantly observed a leucocytosis reaching as high as 21,000 to the cubic millimeter; the increase was essentially polynuclear in type, rarely over eighty per cent. Toward the end of the acute period, as well as during convalescence, the eosinophiles were found rather high (13 per cent.). Sometimes during the febrile period myelocytes were present in two- or three-per-cent. proportions. The joint fluid was examined in four cases and found to contain almost exclusively polymorphonuclear leucocytes.

Histological Diagnosis of Rabies.—The great practical importance of the histological method of diagnosing hydrophobia, recently introduced by Van Gehuchten and Nélis, led CARLOS FRANCA (*Comptes Rendus de la Société de Biol.*, Nov. 30, 1900) to further investigate its usefulness in current practice. The animals made use of by Van Gehuchten and Nélis died as the result of the natural progress of the disease; most of the material sent to laboratories for examination consists on the other hand, of tissue from animals killed before the disease has sufficiently progressed to kill them. To find out in how far the histological method could be relied upon with such tissues was the main object of França. The conclusions of the writer are as follows: (1) In rabid animals which died prematurely the ganglionic cell-changes described by Van Gehuchten and Nélis were sometimes absent. (2) In these animals it is the rule to find round extracapsular elements in greater or less numbers. (3) The bulbar lesions appeared on the whole more intense than those of the ganglion cells. (4) It is impossible to wholly rely on the microscopic findings in the nervous symptoms of prematurely-dead rabid animals in establishing the diagnosis of hydrophobia.

Ascarides Lumbricoides and Appendicitis.—The following observation of ARBORÉ-RALLY

(*Arch. de Méd. des Enfants*, Dec., 1900) is of considerable interest in showing how closely under some conditions the presence of the ascarides lumbricoides in the intestine may induce symptoms simulating those of appendicitis. The case in question was that of a ten-year-old child who had been sick for three days when seen. The patient had been suddenly taken ill with intense pain in the abdomen, followed the next day by vomiting; the bowels were constipated. When first seen the author found the child with fever, rapid pulse (120), and incessantly vomiting. Recurring abdominal pains (intervals of fifteen minutes) and cutaneous hyperesthesia all over the abdomen made palpation difficult. The point of maximum pain was in the region of McBurney's point; there was also considerable abdominal rigidity. On the fourth day the condition became more aggravated, with some tympanites and increased tenderness over the appendiceal region. The condition became so urgent that surgical consultation was obtained; but it was decided to wait a little longer. Finally, during the night of the fourth day of illness, an ascarides lumbricoides, 16 cm. long, was vomited. Thereafter amelioration was quite rapid.

The Bone Lesions of Myxedema.—Most observers who have studied myxedema regard the bone lesions met with in this affection as rachitic in character. SIEGERT (*Archives de Médecine des Enfants*, Dec., 1900), however, in a recently published paper contends that the lesions of the osseous system in myxedema are of a very different character. The author finds, instead of the premature ossification of the long bones in rachitis, a tendency quite the other way in myxedema, as shown by the investigation of Hofmeister upon rabbits. The epiphyseal catilages in lieu of early ossification, as in rachitis, remain cartilaginous more or less indefinitely. The writer further finds that the cartilages at the base of the skull persist, as well as the large fontanelle, in all cases of the congenital form, up to the age of thirty; in some cases even up to forty years. He conculdes thus: (1) The osseous lesions of myxedematous idiocy are specific in character, due to a hypoplastic chondrodystrophy. (2) They are wholly independent of rachitis; they present, on the contrary, a true antagonism to rachitis in their inception, development and results.

Fecal Impaction.—The difficulties and possible errors of diagnosis are illustrated by the following case, says DR. LICHTENSTEIN (*Centralblatt f. Gynaekol.*, Dec. 1, 1900): A few months ago he was hurriedly called in the absence of the attending physician to see a patient in the throes of long retained urine. Before obtaining any history he relieved her with the catheter, after coaxing it past a mass which compressed the urethra against the symphysis pubis and apparently filled the pelvis, of about 850 cubic centimeters of heavy foul urine. He then set about ascertaining the trouble and elicited the fact that the catlieter had been in use for some time, owing to this slowly increasing mass which her physician said was a growth requiring operation, which had been delayed owing to her enfeebled condition. Ordinarily her health had been good, menstruation normal, bowels regular, appetite good. She presented an examination, pallor, accelerated pulse, no fever, general nervousness, fair strength and weight. In the right iliac and lumbar regions were many hard, round, uneven more or less fixed masses, which could be traced downward toward the pelvis. In the midline was the uterus displaced upward out of the pelvis. In the vagina the uterus was out of reach and the relations were distorted by the growth which appeared to be in the cul-de-sac of Douglas. By the rectum this mass was made out to be feces which had accumulated in the rectum, filling it and the pelvis completely, and the sigmoid colon was pushed over to the right. Manual cleaning of the rectum was done and large doses of castor oil ordered each night. For three days she continued to pass inspissated feces until finally her intestines appeared normal. Proper attention to her bowels after that effected a cure.

Bisection of the Uterus in Pelvic Surgery.—H. A. KELLY (*Annals of Gynecol. and Pediat.*, Dec., 1900) describes the following operation for the removal of pelvic inflammatory masses by the abdomen after bisection of the uterus. It is applicable to such cases as present the most dense and extensive adhesions between the uterus and its adnexa and all the surrounding viscera, so that the usual method of dissecting out one adnexum, then the uterus, and finally the opposite adnexum is not possible. The abdominal cavity must be minutely walled off with pads from the pelvis and all abscesses, cysts or hematomata reduced by aspiration to gain space. The bladder is then separated from the uterus and the fundus of that viscus found. In the middle line between two pairs of museau forceps the uterine body is bisected as far as the cervix for a supravaginal hysterectomy and as far as the vagina for a panhysterectomy. As the division is extended downward the clamps are advanced also, so that they act as tractors on the already bisected part. On either side of the cervical halves or stump the uterine vessels are isolated and ligated; each half of the uterus is freed from below upward from its adnexum, until this alone is left on each side for the final dissection in a free field. At times the uterus is adhered directly to the rectum. Then the anterior wall is first divided down to the cervix. Here the vessels are again secured and the uterus freed posteriorly from the rectum from below upward, step by step. As needed pieces of the uterine body may be sliced off if adherent to the bowel. When the uterus is finally free behind the posterior wall is bisected and the procedure as above followed.

Foreign Bodies in the Bronchi.—The peculiar absence of all urgent symptoms and the total recoveries of the following two cases of foreign body in a bronchus are of great interest, says E. F. SYRETT (*Lancet*, Dec. 15, 1900). Case 1., boy, thirteen years old, first seen May 12, 1900, ailing for

three weeks, cough, fever to 103° F., pain in the right chest, flushed cheeks, impaired percussion and deficient breathing over the whole lung, moist râles at the apex in front and behind in the right chest, abundant bloody, mucous expectoration. Rest in bed for two weeks was had, when normal temperature, persistence of the signs, but absence of symptoms induced ambulatory treatment. He was seen each week for the next two months and remained about the same. July 26, 1900, while struggling to take a stick from a dog, a violent attack of coughing came on and a small round pebble like a cherry-stone was expectorated. Recovery followed. It transpired that during a football game he had inhaled this stone while carrying it in his mouth. Case II., a thirty-three-year-old woman on September 12th, 1900, inhaled while under gas a wisdom tooth which the dentist had let slip. She had bloody expectoration and signs of a violent bronchitis over both lungs. On September 25th she coughed up the offender, hitherto not suspected, and went on to recovery.

Paraffin Injection in Incontinence of Urine.—R. GERSUNG (*Centralb. f. Gynaekol.*, Dec. 1, 1900) describes a case of obstinate postpartum vaginovesical fistula cured by operation, but followed by incontinence of urine, persisting for many years. This resisted several interferences, including three torsions of the urethra, following the last of which came gangrene of most of the canal. The patient then came under the author's treatment, which consisted in other attempts to twist the stump of the urethra and neck of the bladder and finally to cause a fold in the neck. Temporary improvement and then relapse occurred. The patient went home to rest in a condition of incessant dribbling while sitting, standing or walking and continence for only a short time and small amount while recumbent. After a while she returned for further treatment which was begun notwithstanding an acute gonorrheal colpitis. July 19th, 1900, under cocaine, paraffin was injected in a ring about the bladder end of the urethra remnant, in the form of unguentum paraffinæ, 3.50 grams. Irrigation was retained. After a few hours catheterizing was necessary and again the next day. After two days there was continence in the recumbent, but dribbling in the erect position of the trunk. July 26th, under cocaine, 2.50 cubic centimeters of the same preparation were injected, reinforcing the former and making a thick ring which was palpable from the vagina, apparent in the vestibule about the neck of the bladder and encroached upon the lumen of the viscus much as a slightly enlarged prostate does in the male. During the next twenty-four to thirty-six hours the patient was harassed by violent urinary tenesmus, recurring every five or ten minutes. Whether this paraffin ring or the complicating gonorrhea was the cause was never determined definitely, but the condition soon improved, and July 31st, at discharge, the patient remained dry in the erect position and in walking for one to one and a half hours. This control increased to five hours during the next three weeks while still under treatment for the gonorrhea. Meanwhile the paraffin mass had not in the least altered. October 25th the patient described her condition as much better; walking about she could hold her water for from four to six hours, for ten hours while resting. While active the bladder would contain about three and one-half deciliters. Micturition was voluntary, but intermittent, a good stream being interrupted at short intervals by brief dribblings until the bladder was empty. This seemed to depend upon respiration. Whether such paraffin injections will be generally serviceable remains to be proved, but the condition of this woman three months after treatment indicates that it has possibilities worthy of trial.

Prophylaxis in Asepsis.—A. HAMMESFAHR recognizes that the hands once infected cannot be rendered absolutely germ-free the same day (*Centralbl. f. Chirurg.*, Nov. 24, 1900), although it is possible to so reduce the number of germs as to render infection unlikely or trivial so that the ordinary body resistance will successfully combat it. Prophylaxis against inoculating the hands is the best and supreme method of acquiring asepsis and it is a duty alike to the surgeon, assistants, nurses and other attendants. Examination and treatment of all the body canals and cavities should be done with hands or at least fingers protected with rubber gloves or stalls against contamination, notably the mouth, throat, vagina and rectum. Bad teeth or other oral disease in the surgeon should be cured lest by cough or speech the wound become inoculated. The hair of the scalp and face should be kept closely cut. Seborrhea must not be tolerated. A beardless face is best. In removing dressings only instruments should be used and when these fall upon the operating-room floor attendants should handle them only with special forceps. After a septic operation has been done nothing in the room should be touched until the hands and gloves are cleaned, such as door-knobs, water-faucets, furniture, etc., which thus smeared can infect the next comer. For most operations rubber gloves, head bandage and all other precautions are commended. In ordinary social and professional relations some glove protection of the hands is advised to avoid the likelihood of infecting the skin unawares. In general terms such rational straightforward guardedness is enjoined upon the internes, who must not evacuate an abscess and then attend a confinement.

New Craniectomy Instruments.—L. GIGLI (*Centralbl. f. Chir.*, Dec. 1, 1900) claims the following advantages for his new craniectomy set: Simplicity, asepsis, rapidity, certainty and universal application. It comprises a special boring mill, curved hollow sound with traveling hook on a wire running in its center and a thread carrier. The borer consists of a large deeply corrugated, horizontally placed handle for the left hand to grasp. Through the body of this handle passes a short shaft horizontally and at right angles to the same. On this shaft plays a cogged pinion with the usual handle for turning it. The shaft which carries the drill is vertical to the foregoing and at its top has a small wheel meshing with the drive wheel. The depth of the hole is fixed by an adjustable guard

whose face is across the axis of the drill. The cleanest and most rapidly drilled holes are given by the ordinary carpenter's auger-bit, with a central screw center and two lateral cutters. The diameter of the holes is best four to six millimeters. The curve of the sound is such that it can be passed through such a hole, between the dura and the bone and the position of its point is estimated from the direction and place of its handle. A little beyond this point the next hole is to be drilled. The thread-carrier is made of two small curved hollow staffs opposed to each other along their long axis and hinged at two places. At their center is a device by which the points may be separated or approximated and at the end of the shank is the handle which fastens off the thread. This starts down one staff out of its point, across to and into the point of the other, and so back to the handle. With the thread in position when the points are separated, it passes straight across the interval and where it is easy of access by the traveling hook of the hollow sound. Through the second hole the thread carrier is therefore passed and opened. The hook soon finds the thread and pulls it through the first hole with the wire saw following. Then the cut through the bone is made. The rapidity and very slight loss of substance of the bone commend it greatly.

Heart Reflex.—Some time ago a peculiar phenomenon, known as the lung reflex, was described by A. ABRAMS, which consisted in a dilatation of the air vesicles and a partial obliteration of the cardiac, liver and splenic dulness as a result of cutaneous irritation. He now describes and illustrates (*Med. Rec.*, Jan. 5, 1901) another condition called the heart reflex, which he has fully investigated and believes will be of considerable value in the future. He has found that if the skin in the precordial region be vigorously stimulated by rubbing with a blunt instrument, such as an eraser, a contraction of the myocardium is observed. The contraction is not sudden or of momentary duration, but lasts usually not less than two minutes and remains after the stimulation has ceased. In individuals with dilated hearts the reflex is very evident and of much longer duration than in normal hearts, and the nearer we approximate the precordial region with a fluoroscope and the more vigorous the cutaneous irritation, the more decided will be the change. The value of this sign can be readily appreciated in differentiating between a dilated heart and pericardial effusion. In estimating the amount of reduction of cardiac dulness, it is necessary to wait two minutes after the application of the stimulation, for the lung reflex which causes a diminution in cardiac dulness is not abolished until the end of that time. Although this strange reaction is better demonstrated by the fluoroscope, percussion is also at times very satisfactory.

Anteroposterior Subdivision of the Bladder.—EUGENE FULLER (*Jour. Cutaneous and Gen.-Urinary Dis.*, Dec., 1900) reports in detail two cases of this rare and interesting anomaly. These are, the writer believes, the first cases of this anomaly to be reported. In both these cases the tranverse partition lay anterior to the ureteral openings so that all the urine first entered the posterior vesical chamber. The anterior chambers were small, holding about an ounce to an ounce and a half, with rigid walls, while the posterior ones were roomy and distensible, comparing closely in those respects with the normal vesical cavity. The two chambers were connected in the upper middle portion of each partition by an oval aperture, and capable in one case of admitting at once the tips of the fore- and second finger. The vertical diameter was the greater. In the other case the connecting aperture was so narrow that it could admit only the tip of the forefinger. This aperture was round. In this case the bladder cavity resembled an hourglass except that the posterior vesical chamber was larger than the anterior. In both cases the distance from the base of the bladder to the lower margin of the aperture was much greater than from the upper margin of aperture to the superior wall of the bladder. In both instances the partition was very thick. In one case the cavity of the anterior chamber was irregularly spanned by numerous fine fleshy columns similar to the columnæ carneæ of the heart. The marked clinical feature in these two cases was the slowly-increasing difficulty in urination. This began in early life and finally ended with retention. This difficulty had been so gradual that a maximum amount of compensatory hypertrophy had developed in connection with both the vesical and abdominal walls. Both patients had urethral strictures, but this condition appeared to be a late and more or less accidental condition. Both gross and histological examination of the specimens showed that the prostate did not enter into the formation of the anterior chamber.

An Unusual Estivo-autumnal Case.—Malaria frequently causes such peculiar groups of symptoms that the microscope is the only means by which diagnosis can be made. G. L. PEABODY, (*Med. Rec.*, Jan. 5, 1901) reports the case of a patient who was received in the New York Hospital, suffering from severe headache which had recurred nearly every afternoon for six months, coming on about three o'clock and lasting usually until eight or nine o'clock in the evening. The patient had never had a chill, but his headache was accompanied by considerable fever, and for several months there had also been added to his daily distress severe attacks of abdominal pain, starting near the umbilicus and radiating toward the left kidney. The pain was sometimes relieved by walking and always by vomiting, so that the latter was frequently induced. The splenic area of dulness was increased and a firm, hard mass could be felt in the left hypo-chondrium, not extending beyond the free border of the ribs and not movable with respiration. The blood showed the presence of crescents, and the patient was put upon quinine, gr.

xv a day, and Fowler's solution, ♏ iij, after each meal. After two weeks his attacks of headache, pain and fever had subsided, the spleen was movable with respiration and palpable. It is believed that the pain was caused by adhesions binding the spleen down and resisting the enlargement of that organ.

THERAPEUTIC HINTS.

Melancholia.—These patients, says Mr. Allen Starr, cannot be diverted and amused as they are exhausted and distressed and must not be encouraged to make efforts, therefore a quiet country place is most suitable. The food must be nutritious and easily digestible, and must be helped out by stimulants as wine or milk-punches. Intestinal antiseptics such as sodium benzoate, salol, or enteric pills of potassium permanganate, cardiac stimulants, vasodilators, and glycerophosphates, gram 1.0 (gr. xv), tid., constitute the routine medication. Warm baths and alternating hot and cold douches are beneficial. Morphine does not cause the habit and is specific in relieving the mental symptoms; it may, however, constipate. A good formula is:

℞ Morphin. bimeconat.
Aloin ....aa. 0.003 (gr. $^1/_{20}$)
Strychnin .... 0.0006 (gr. $^1/_{100}$)

Insomnia must be prevented by hypnotics, different types of these being used on successive nights.

Gastrospasm.—The treatment, write Van Valzah and Nisbet, is almost exclusively dietetic In the beginning the diet should be soothing and small in quantity, as hot milk. The amount should be gradually increased, and after a week cereals, and later meats may be added, so that the stomach may gradually be rendered tolerant of larger and larger quantities of food. The bromides act only as palliatives, cannabis indica is uncertain, and belladonna is of no benefit. Aconitine and codeine in combination are of the greatest value. Vigorous massage is beneficial, and sedative galvanization and a hot compress may be tried.—*Diseases of the Stomach.*

Impetigo Contagiosa.—Scrub with warm water and soap, writes Geo. T. Jackson, and cover with 5-per-cent., carbolized vaseline, or oxide-of-zinc ointment with 5-per-cent. carbolic, or with 5-per-cent. ointment of ammoniated mercury. If crusts are present, remove by soaking with oil or warm water; if bullæ, prick at their most dependent part and let the fluid escape.—*Diseases of the Skin.*

Acute Epididymitis and Orchitis.—The treatment, writes Hermann Tillmanns, includes energetic catharsis at the outset, elevation of the scrotum, absolute quiet, and the application of ice. Repeated warm baths diminish the pain, or hypodermics of morphine, or rectal narcotic suppositories. The galvanic current also gives relief, the positive pole being placed on the testicle, and the negative pole on the cord. The author also likes inunctions of blue ointment. When the acute inflammation is over, employ moderate compression, preferably by an India rubber suspensory. Strapping the scrotum with strips of adhesive plaster is not only unpleasant to the patient, but also dangerous. If the patient can walk about, the scrotum is besmeared with vaseline and covered with rubber tissue with a hole for the penis, then with cotton and a suspensory, so that by the perspiration that forms on the scrotum the whole dressing makes an efficient means of applying moist heat.—*Text-Book of Surgery.*

Catarrh.—In nasopharyngeal and aural catarrh associated with anemia, Lennox Browne prescribes:

℞	Tinct. ferri chlorid..	0.65-1.3	(♏ x-xx)
	Ammon. chlorid.....	0.65-1.3	(gr. x-xx)
	Aq. chloroform.....	15.0	(℥ ss)
	Aqua. q. s.....ad.	30.0	(℥ j)

M. The sal ammoniac appears to aid the assimilation of the iron.—*Diseases of the Throat and Nose.*

Smallpox.—Quinine, in doses of 0.35 gram (gr. v) doses with camphor, 0.2 (gr. iij), and tincture of perchloride of iron are, writes J. W. Moore, the most valuable internal remedies. The following is useful:

℞	Tinct. ferri perchlor... ...	8.0	(℥ ii)
	Acid. phosphor. dil.....	6.0	(℥ iss)
	Glycerin	10.0	(℥ iiss)
	Tinct. aurant.....	15.0	(℥ ss)
	Ap. chlorof. q. s.....ad.	180.0	(℥ vj)

Sig.: One ounce every six hours.

A palatable effervescing chalybeate is a mixture of a tablespoonful of:

℞	Ferri et ammon. cit.	8.0	(℥ ij)
	Ac. citrici.....	10.0	(℥ iiss)
	Aquæ. q. s.....ad.	180.0	(℥ vj)

with two tablespoonfuls of:

℞	Potassii bicarb.....	20.0	(℥ v)
	Spt. chlorof.....	8.0	(℥ ij)
	Aquæ. q. s.....ad.	360.0	(℥ xij)

Light should be kept from the face, and the surface heat and vascularity regulated by light poultices over the entire face, or a mask of lint steeped in glycerin and water, and covered with oiled silk. This excludes air, keeps the parts moist, lessens irritation, and so favors the prevention of pitting. Antiseptic and astringent dusting powders are comforting to the skin, such as boric acid, bismuth subgallate or:

℞	Ac. carbol.....	2.0	(℥ ss)
	Zinci oxid.....	30.0	(℥ j)
	Lycopod	30.0	(℥ j)

The crusts should be separated early by linseed poultices. In the bad cases the delirium, the fetor, and the pain seem to be rapidly overcome by warm baths and alcoholic stimulants. Affections of mouth, tongue, and pharynx are best treated by ice and antiseptic sprays. Diarrhea may be controlled by starchy foods, by a poultice or wet compress on the abdomen, or by intestinal astringents.—*Twentieth Century Practice.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JANUARY 19, 1901.

IN 1800.

The nineteenth century has been an age of experimental creation in medicine. Innumerable facts have been gathered by diverse men in a slow, minute, painstaking fashion, and here and there, at some master touch, the seeing eye has discerned that underlying the scattered particles of fact there is a fundamental principle that, like a magnet, draws them all into correlation with each other.

The progress thus made in one hundred years is startlingly apparent in reading old text-books by the great medical men of the eighteenth century. The gaps they strove to bridge, the shrewd guesses at causes which the poor microscopes of the day had not revealed, the foreshadowing of treatment that is to-day established by experiment, all indicate how great has been the march toward health by the discovery of hitherto hidden principles.

A Century's Retrospect of Medicine forms the contents of the last number of the old century of the *British Medical Journal*, and in the series of papers describing the medical ideas in 1800, we find a picture of the times and conditions of hygiene and medicine that stimulates us to an appreciation of many nineteenth century blessings that we have learned to take for granted.

In a day when ladies wore low-necked and short-sleeved dresses out-of-doors in all weathers, and when the whole community was guiltless of woolen underclothing, and when no man would carry such a feminine thing as an umbrella, there was plenty of opportunity for pneumonia, "in which condition," says an eighteenth century textbook, "the lungs are sometimes converted into a solid substance very much resembling the liver." In an age when everybody ate too much, and drank to excess, digestion was but little understood. It was taught that digestion was performed in the stomach, and was no other than a corruption or putrefaction of food, performed by a menstruum that was chiefly saliva, for it was not until 1824 that Dr. Prout discovered hydrochloric acid in the gastric juice, and 1836 when Schwann isolated pepsin.

In Lambert's History of London (1806) we read, "No city in the world is better supplied with water than London, every house in which may receive a regular supply of this necessary article three times a week by paying a moderate annual sum to one of the water companies." The possibilities of hygienic living in 1800 were further limited by the use of cesspools, the total lack of bathrooms, and the evils of poor and inadequate drainage and ventilation, to say nothing of the absolute ignorance of the community on the subject of infectious diseases.

The great discoveries of the century cluster naturally around the discovery of germs, as the bearers and propagators of contagious diseases, and the discovery of antiseptics; but hardly less have the great advances in chemistry and biology opened the field for correct investigations in anatomy and physiology and every other branch of medicine.

One hundred years ago the nature of the secretions of the body was almost unknown, the mechanism of respiration was not understood, nor were the abnormal signs of it recognized until the stethoscope was applied. It was taught, in connection with the nerves, to quote one authority, that "from the vessels of the cortex a liquor is separated into the hollow pipes of the medulla which are continuous with the small tubes of the nerves even to their soft, pulpy extremities, so as to be the cause both of sense and motion." Concerning the brain the chief interest lay in determining the seat of the soul.

In 1800 the Retreat at York had been established for eight years, and the system there adopted of treating the insane with humanity

aroused a frantic opposition, for the chain, manacle and muzzle method of relieving the community from the insane was in vogue. One-half the lunatics in Great Britain were not provided for, and, owing to the scanty accommodations in asylums, many were detained in prisons or workhouses, or chained in the cellar or in the garret, or else allowed to wander half-naked through the country. But the lot of these was considered enviable compared with that of those who were cared for in "madhouses," for the lunacy laws offered no legal protection for the insane. The generally-accepted method of treatment for insanity was described in 1900 as follows: "Patients are ordered to be bled about the latter end of May, according to the weather; after they have been bled they take vomits once a week for a certain number of weeks; after that we purge the patients."

In the last hundred years, smallpox as an epidemic has become a disease less to be feared than measles. Scurvy, the bane of sailors in the eighteenth century, is almost a disease of the past. Jail-fever has gone forever from the prisons; and hospitals, the greatest beneficence to science and to the sick, have grown to their present number and condition.

And yet it is not with the presumption of having acquired all knowledge that these men have reviewed the century's progress; but with a humility mingled with confidence that the advances which will be made in the next hundred years will show the knowledge of the present to be as inadequate and antiquated as that of a hundred years past in the light of to-day.

NEW YORK'S UNDERGROUND RAILROAD AND PUBLIC HEALTH.

From present indications the long-talked-of underground railroad is at last to become a reality. The undertaking, as is inevitable with any great innovation, is attended by many inconveniences and minor evils, not the least of which is the impassability of the streets where excavating is in progress. Even with the best possible arrangements for removal of *débris* and the speedy execution of contracts, New York must long suffer the presence of unsightly ditches in her thoroughfares and the unavoidable interference with business and travel.

Apart from the inconvenience there seems to be in the minds of many persons a fear that the excavations will be detrimental to health, chiefly by causing an epidemic of malaria. The idea that malarial germs are set free by exposing upturned earth is one of the popular misconceptions that is rapidly going out of fashion even in the minds of the laity.

Were the history of the *Anopheles* and its development in pools of stagnant water better understood this uneasiness would be readily allayed. In this connection it is well to remember that the cases of malaria appearing in our hospitals and clinics and sometimes in private practice hail usually from Jersey City, Long Island or the Bronx, where the extensive low-lying and swamp-grounds offer to the *Anopheles* exceptional breeding facilities. On Manhattan Island, however, owing to its extremely rocky formation, one rarely finds these conditions, consequently malaria is uncommon in this most populous portion of New York.

That it will increase does not seem probable, as it is not the mere turning-up of the earth, but the formation of pools from the possible bursting of a pipe or a heavy rainfall that causes the danger. Such pools, if allowed to collect and stagnate, might cause the excavations to become a menace to health, but proper drainage will be provided and precaution taken against such emergencies. Consequently there will be small chance for the breeding of any stray *Anopheles*.

The possibility of any outbreak of disease of any kind is rendered still more remote by the wise provision which enacts that the work shall be done in sections, each of which shall cover not more than 400 yards, so that each excavated portion can be built in and finished with greater dispatch and less risk to health than if larger areas were opened.

One feature of the question which suggests an important topic is in reference to the constant escape of illuminating gas into the atmosphere. While the amount of this gas which may be found in the air must be small, certain effects are known to follow the constant inhalation of even minute quantities of this gas. Workers about gas factories and foundries, bakers, cooks and laundresses, are known to suffer from the effects of too much carbon-monoxide gas. The most important symptom is a peculiar type of anemia, due to the destructive action of the gas on the red blood-cell. Bronardel has shown that choleraic symptoms are not infrequently observed under similar conditions and peculiar muscular pains are frequently observed.

It seems not unlikely, therefore, that among those living in close proximity to the open cuts of the underground a certain amount of chronic gas-poisoning may be expected.

The destruction of the beautiful shade-trees along the Western Boulevard is one of the regrettable incidents of the work, but it cannot be said to affect the city's health adversely. Unfortunately the dwellers in the rocky sections must suffer inconvenience from the severe blasting, but as this, according to law, must be done only during certain hours of the day, the nuisance will be considerably minimized. The only persons, therefore, who will be unpleasantly affected are invalids and those suffering from neurasthenia.

In any enterprise of such magnitude, drawbacks of a more or less serious nature are unavoidable, but from present indications the completed work will justify the discomforts incidental to so great an undertaking.

ALFRED RUSSEL WALLACE AND VACCINATION.

WE are in the midst of reviews of the past century's work in all branches and the progress in medicine, because of its universal interest, has come in for even more than its share of laudatory review. As a rule, the opinions expressed on advances in medicine have been worthy of the magnificent development that has taken place.

No better exemplification of the maxim that the shoemaker should not go beyond his last has been furnished for many years, however, than the failure of even scientific minds to understand the significance of certain phases of medical progress. The most glaring example of the failure of a great scientific mind to appreciate a distinct medical advance is afforded by Alfred Russel Wallace's judgment of the value of vaccination.

"The Wonderful Century," the volume in which the sharer with Darwin of the development of the theory of evolution expresses his views as to scientific progress during the past hundred years, was published some time ago, but has taken on a new interest in these last few weeks, because of the oft-quoted chapter "Vaccination a Delusion." Wallace does not mince words in his declaration of opinion. He thinks that he can satisfy his readers of the certain and absolute uselessness of vaccination as a preventive of smallpox. "Vaccination," he declares, "is a gigantic delusion. It has never saved a single life. It has been the cause of so much disease, so many deaths, such a vast amount of utterly needless and altogether undeserved suffering, that it will be classed by the coming generation among the greatest errors of an ignorant and prejudiced age, and its penal enforcement will be considered the foulest blot on the generally beneficent course of legislation during the century."

Needless to say this tirade is only the wild vaporing of a fanatic antivaccinationist. Vaccination has constantly grown in medical favor all over the world during the last twenty-five years. The more thoroughly it has been tried, the more confidence has it elicited in its power to protect. The armies of Europe present the best proof of this. They are ruled by men who would soon do away with the bother of vaccination were it not for the profound and growing conviction that to Jenner's discovery and its universal application are due the modern freedom from smallpox in camp and barracks. The disease was one of the worst and most feared scourges of army life, and is now almost unknown.

Mr. Wallace's surprising declaration can be properly understood only by a knowledge of his views on other matters related to medicine, of which he knows as little and has perhaps even less reason for his opinions than on vaccination. In the same volume, in his essay on "The Neglect of Phrenology," he says: "In the coming century phrenology will assuredly attain general acceptance. It will prove itself to be the true science of mind. Its practical uses in education, in self-discipline, in the reformatory treatment of criminals, and in the remedial treatment of the insane, will give it one of the highest places in the hierarchy of the sciences, and its persistent neglect and obloquy during the last sixty years will be referred to as an example of the almost incredible narrowness and prejudice which prevailed among men of science at the very time they were making such splendid advances in other fields of thought and discovery." Almost as erratic are Mr. Wallace's utterances on hypnotism and psychical research. "Thought transference," he says, "automatic writing, trance-speaking, and clairvoyance have been all demonstrated in the presence of living observers of undoubted ability and knowledge. The still more extraordinary phenomena—veridical hallucinations, warnings, detailed predictions of future events, phantoms, voices or knockings, visible or audible to numerous individuals, bell-ringing, the playing on musical instruments, stone-throwing, and various movements of solid bodies, all without human contact or any discoverable physical cause, still occur among us as they have occurred in all ages. It is absolutely certain that during the coming century they, too, will be accepted as realities by

all impartial students and by the majority of educated men."

Verily the prophetic picture the great evolutionist draws for us of our state of mind in the century we are just entering is not very attractive. Fortunately there is no guarantee that Mr. Wallace is either a prophet or the son of a prophet. We can then contemplate with more peace of mind than might otherwise be possible the prospective opinions by which the rising generation are to be ruled. Had his views on vaccination been given to a hero-worshiping public by themselves, without the precious antidote of his other opinions, there is in them the possibility of working. His antivaccinationism, taken in connection with the equally aberrant fancies in other fields of thought allied to medicine, only emphasizes the old, old lesson, *sutor ne supra crepidam*.

In our day of scientific specialization no one mind can appreciate the significance of progress in widely separated branches of science. To attempt to do so is to invite inevitable failure and to make oneself absurd. This Mr. Wallace has done very effectually. When Tennyson was uttering some of the senilities that even his greatest admirers found it difficult to bear with equanimity, there was many a heartfelt wish that we could muzzle our poets in their day of senile degenerescence. It would seem from Mr. Wallace's twaddle that a like procedure would be eminently desirable for our men of science also as they grow old. The age-limit of rational opinion would be hard to decide, but the world would be spared so much nonsense that it could afford to lose some sparks of sense that might be missed if a gag-law were enforced after a certain age.

ECHOES AND NEWS.

NEW YORK

Alumni Association of the College Physicians and Surgeons.—This Association held its annual smoker at Sherry's last Monday evening.

Manhattan Dermatological Society.—This has just been organized with President, Dr. W. S. Gottheil; Vice President, Dr. L. Weiss; Secretary, Dr. Jacob Sobel.

Grip Cases Break the Record.—The record of last week's deaths from all causes shows a phenomenal increase in the number of those past their seventy fifth year. At that age an attack of the grip so weakens the system that the patient succumbs. It is to be hoped that the worst is past and that with favorable weather and extra care the disease will gradually die out.

Dr. Leverson Still Advertising.—The Health Board held a meeting last week, but took no action in the case of Dr. Montagu R. Leverson, the Brooklyn physician who has been reported as having said that he had treated many cases of small-pox without reporting them to the authorities. A demand has been made on Dr. Leverson to make affidavit as to whether he has or has not treated small-pox cases without reporting them, and it was said that the Board was awaiting this reply.

Site for Tuberculosis Hospital Approved.—The State Forest Preserve Board approved of the site at Raybrook, between Saranac Lake and Lake Placid, selected by the trustees for the proposed State Tuberculosis Hospital on January 10th. The purchase price agreed upon was $7500, which is $2500 less than the sum which was first asked. The Raybrook site is not near the camp-sites of any individuals and there was no opposition to it. It comprises a little over 521 acres and is about three miles southeast of Saranac village.

Kings County Medical Society.—After a spirited contest the following officers were elected at the annual meeting, Tuesday, January 15th. President, William Browning, M.D.; Vice-President, H. A. Fairbair, M.D.; Secretary, D. Myerle, M.D.; Associate Secretary, W. S. Hubbard, M.D.; Treasurer, O. A. Gordon, M.D.; Associate Treasurer, J. R. Stivers, M.D.; Librarian, J. M. Winfield, M.D.; Censors, W. C. Wood, M.D., J. E. Sheppard, M.D., J. M. Van Cott, M.D., R. J. Morison, M.D., J. P. Warbasse, M.D.

State Board of Health Protest.—The State Board of Health met in Albany January 10th. The Board believes it would not be in the interest of economy, as suggested in the message of Governor Odell, to have the present nine Commissioners replaced by a single-headed commission. After the meeting Dr. Daniel Lewis of New York, President of the Board, Dr. D. W. Smith of Syracuse, Dr. S. Case Jones of Rochester, Attorney General Davies and Owen Cassidy of Montour Falls, members of the Board, together with Dr. Baxter T. Smelzer, its Secretary, called on the Governor and protested against any change, on the ground that it must necessarily cost the State more money.

Work of the Babies' Hospital.—The Babies' Hospital of the City of New York held its annual meeting last evening, and the following officers were re elected for 1901: President, J. Hooker Hamersley; Vice-President, Oliver G. Jennings; Treasurer of Current Funds Mrs. John B. Calvert; Treasurer Permanent Fund, Henry R. Kunhardt; Treasurer Building Fund, Felix M. Warburg; Secretary, B. Ogden Chisolm. On the Medical Board for the coming year are: Consulting physicians, Drs. A. Jacobi, E. P. Kinnicut Pearce Bailey, Thomas E. Satterthwaite, E. B. Bronson; consulting surgeon, Dr. Robert Abbe; attending physicians,

Drs. L. E. Holt, R. B. Kimball; attending surgeon, Dr. Arthur L. Fisk; consultant, eye and ear, Dr. Wilbur A. Marple.

Elmira Reformatory.—According to the report of the new Board of Managers of the Elmira Reformatory, tuberculosis has increased among the prisoners. The report says that many have the disease when they arrive; others develop it under the trying conditions of prison life, and association with those already affected. The management has become convinced that prisoners healthy upon their arrival become affected, and sometimes with astonishing rapidity, by the disease by being steadily confined in the same cell with a consumptive subject. A case of this kind has come to light, that of a healthy patient, who died within six months after he was confined in the reformatory. The report also says that insanity is on the increase in the institution. "As with tuberculosis," the report says, "no careful medical examination has been made to detect its existence in the entering or departing prisoner, and no minute analysis of the population to eliminate from routine requirements those whose mental conditions rendered their compliance difficult or impossible. Under this system there exists at least one well-attested case of long continued punishment inflicted upon a prisoner mentally irresponsible. That insane persons are frequently sentenced to the Reformatory may excite surprise, but it should be remembered on behalf of the courts that they have no expert means of detecting it and that it is often unsuspected. That this is not always the case, however, is shown by the sentencing of a prisoner to the Reformatory by the Supreme Court sitting in Buffalo in October of this year. The prisoner was examined by two reputable physicians, duly appointed commissioners in lunacy, and adjudged a 'high-grade idiot.'" The report criticises the present "inmate monitor" system and says no good can be brought about by utilizing prisoners to watch over others, and recommends that thirty additional guards be employed. The Board says that much of the damage done to the machinery and the plant in general can be traced to the fact that prisoners were used instead of skilled labor.

Dr. J. Henry Fruitnight.—The following resolutions were adopted at the annual meeting of the Northwestern Medical and Surgical Society:

Whereas, It has pleased Divine Providence to sever by death the membership of Dr. J. Henry Fruitnight in the Northwestern Medical and Surgical Society, a membership lasting nearly a quarter of a century; and,

Whereas, We, the members of this Society, desire to place on record our appreciation of the noble and self-sacrificing character of our late colleague, sadly cut down in the prime of life; therefore be it

Resolved, That in the death of Dr. Fruitnight this Society has lost a modest and congenial companion, a true friend, and a valued professional colleague, whose earnestness of purpose and unselfishness of motive peculiarly fitted him for a large and useful medical career; that he is a severe loss to this Society in which he took a warm personal interest, to the many other medical bodies of which he was a member, and also to the medical profession and the entire community; that his published writings, concise discussions and discriminating thought are worthy of our highest regard;

Resolved, That we sincerely extend our heartfelt sympathy to the members of his bereaved family, wishing for them that consolation which the memory of such a noble life alone can give;

Resolved, That a copy of these resolutions be spread upon the minutes of this Society; that duplicates be sent to the MEDICAL NEWS, the *Medical Record*, the *New York Medical Journal*, *Archives of Pediatrics* and *Pediatrics*, and that an engrossed copy be prepared for the family of the deceased. A. M. Jacobus, M.D.; Edward S. Peck, M.D.; A E. Bieser, M.D., *Committee*.

The Late Dr. Horace T. Hanks.—At the annual meeting of the Medical Association of the Greater City of New York, held at the New York Academy of Medicine on January 14, 1901, the following report was presented: The Committee appointed by the President, Dr. Weir, at the December meeting of this Association, to prepare a suitable minute in regard to the death of Dr. Horace Tracy Hanks, begs to report as follows:

"It is with sorrow that we are called upon to report the death of Dr. Horace Tracy Hanks, one of the Charter members of our Association. Dr. Hanks died of Bright's disease at his home, in this city, on November 18, 1900. He was born in East Randolph, Vermont, on June 27, 1837. He was graduated from the Albany Medical College in the class of 1861. After serving in the Union Army as acting assistant surgeon for two years, he began the practice of medicine in Royalston, Massachusetts, where he remained, however, for a short time only, removing to New York City. He held many positions of responsibility, among which were the professorship of the diseases of women in the Post-Graduate Medical School and attending surgeon to the Woman's Hospital in the State of New York. He was consulting gynecologist to the Tarrytown, Mount Vernon, and St. Joseph's Hospitals. He was a member of the New York Academy of Medicine, the New York County Medical Society, and of the American Medical Association, and was a Fellow of the American and of the British Gynecological Society. Henry D. Nicoll, M.D.; Clement Cleveland, M.D.; Edward E. Tull, M.D., *Committee*.

PHILADELPHIA.

Resignation of Dr. Cattell.—Dr. Henry W. Cattell has resigned the position of pathologist to the Pennsylvania Hospital.

Wills Eye Hospital.—Dr. John Welsh Cros-

key has resigned the position of surgeon and has been succeeded by Dr. McCluney Radcliffe.

Philadelphia Medical Club.—At the annual meeting of the Club, held January 11th, Dr. Edward L. Duer was elected president. The vice-presidents are Dr. John B. Deaver and Dr. Philip Marvel, and the secretary, Dr. Guy Hinsdale, and the treasurer, Dr. F. S. Pearce. The membership is now 313, an increase of 69 during the year.

Influenza Epidemic.—Influenza is epidemic in this city at present, the number of cases being estimated at 70,000. The disease is as yet of a mild type, only five deaths being attributed to that cause during the past week. Reports from Pittsburg indicate that while the disease there is also of a mild type, an unusually large percentage of the cases show varying degrees of mental disorder.

A New Course in the University.—Dr. W. G. Spiller, who has recently been appointed demonstrator of neuropathology offers, beginning about February 1st, 1901, to a limited number of students in that institution, and moreover to a limited number of graduates in medicine who desire to avail themselves of an opportunity to become practically familiar with the anatomy of the central and the pathology of the entire nervous system, an elective course in those branches. This course will comprise the preparation by the students of a series of slides from the medulla oblongata, pons, cerebral peduncles, and basal ganglia.

Dr. Osler's Address on Perforation and Perforative Peritonitis in Typhoid Fever.—Dr. William Osler of Baltimore, present by invitation at the meeting of the Philadelphia County Medical Society, January 9th, delivered an address on "Perforation and Perforative Peritonitis in Typhoid Fever." Dr. Osler stated that changes in nursing and treatment have greatly reduced the mortality of typhoid fever, although the profession cannot congratulate itself on having lessened the incidence of the disease. The mortality should not now be greater than 7.5 per cent. in hospital practice. One class of formerly fatal cases, namely, those suffering from severe toxemia, has been greatly influenced by modern non-medicinal treatment. Of every 100 deaths from typhoid fever only 50 are due to asthenia, 30 being caused by perforation, and 20 by other complications. In contrast to the toxemic cases mentioned there has been no material change in the percentage of deaths from perforation. Two clinical features of this complication are to be emphasized, first, its uncertainty and variability, and, second, the necessity for a complete revision of the methods of observing and recording the symptoms. In this connection two conditions are to be differentiated—the perforation itself and the consecutive peritonitis. It is of the greatest importance to recognize perforation and to operate within twelve hours. Dr. Osler gave in detail the notes of three cases, each one being representative of a type. The first was operated upon nine hours after perforation and died on the third day. The wound in the bowel had almost healed and the patient had undoubtedly died from typhoid fever itself and not from peritonitis following perforation. In a second case operation revealed two perforations, fecal matter in the pelvis, and the gut in such a necrosed condition that it would not hold sutures. The patient died on the table. This belonged to a class of cases in which fatality is inevitable. The third case was operated upon seven and one-half hours after perforation and made an uneventful recovery, illustrating a class in which operation saves life. A careful study of symptoms has shown that the time-honored ones of sweating, Hippocratic facies, feeble-running pulse, collapse, etc., belong not to perforation but to peritonitis. A fuller knowledge of the symptoms of perforation is needed. Dr. Osler does not believe that much good will result from investigating the so-called preperforative stage, but it is the duty of physicians to study carefully the earliest signs of perforation. A study of the hospital notes of cases will convince anyone of their insufficiency. Every serious case of typhoid fever should be watched by a careful physician who is in constant touch with a surgical colleague. It is better that the patient be watched by a skilled resident physician than to trust to the occasional visits of an attending physician.

Dr. Osler gives specific instructions regarding certain points to be noted by the attendants of a severe case. (1) The night nurse or superintendent is to at once notify the physician of the onset of pain, hiccough, vomiting, increase of pulse or respiration, sweating, or collapse. (2) The character of the pain is to be noted (*a*) as to its onset, whether an aggravation of previous pain or a sudden pain recurring in paroxysms; (*b*) as to its locality, whether diffuse or local, in the iliac fossa or hypogastric region, if it radiates—especially to the penis. (3) State the condition of the abdomen as learned by (*a*) inspection—whether flat, scaphoid, or distended. If the latter, is it uniform or in certain regions. Note respiratory movements; (*b*) palpation—note tenderness, muscle rigidity or spasm; (*c*) percussion—note the condition of the flanks and the extent of liver dulness. The latter should be mapped out every three hours, as it may be obliterated in a flat as well as in a distended abdomen; (*d*) auscultation—note degree of peristalsis and the occurrence of friction sounds; examine the rectum and stools. (4) Observe the general condition of the patient as evidenced by change in expression, pallor, pulse, temperature, respiration, sweating, vomiting, hiccough. (5) Examine the blood. Note if leucocytosis is present, and if so whether stationary or rising. The leucopenia of typhoid fever must not be forgotten in this connection.

An important preliminary to the further reduction of the mortality from typhoid fever is the practical firsthand instruction of senior medical students. This does not mean lectures or recitations, but actually seeing cases and watching their

progress. Dr. Osler referred to the mistakes in diagnosis made by the army surgeons during the Spanish-American war as evidence of the lack of knowledge of typhoid fever, not more than 50 per cent. of the cases being diagnosed as such before they were sent to hospitals. By carefully watching for symptoms of perforation, in severe cases and operating at the earliest possible moment it is probably possible to save one-half of them. Eleven cases of perforation occurring in the wards of the Johns Hopkins Hospital have been operated upon with five recoveries. Out of five additional cases operated upon at once after admission there was one recovery.

CHICAGO.

Bequest to Presbyterian Hospital.—According to the will of Mrs. Aurelia B. King, widow of Henry W. King, which was recently filed in the Probate Court, the Presbyterian Hospital of Chicago receives $1000.

Will of Mr. H. W. Jackson.—According to the will of the late Mr. Jackson, which was recently filed in the Probate Court, the Presbyterian Hospital, the St. Luke's Hospital, and the Chicago Hospital for Women and Children will receive $1,000 each.

Medical Society of Rush Medical College.—Recently a Society was organized by the Faculty of this College. Dr. James B. Herrick was elected secretary. The presiding officer will be selected at each meeting. Those composing the Executive Committee are Drs. Frank Billings, Ludwig Hektoen, J. Clarence Webster, L. F. Barker, and Dr. Herrick. The meeting will be held monthly.

Lodging-Houses.—Of the 815 lodging-houses in this city, all of them are conforming to the health laws, according to the annual report submitted by the chief sanitary inspector. It is recommended to the State Board of Health that a room be set aside in each lodging-house where cases of infectious disease can be quarantined temporarily. During the nine months from April 1st to December 31, 1900, 90 suits were brought against owners of houses for violations of the health laws.

Chicago Ophthalmological and Otological Society.—At a meeting, held January 8th, 1901, the election of officers for this year resulted as follows: President, Dr. Casey A. Wood; Vice-President, Dr. William H. Wilder; Secretary-Treasurer, Dr. C. P. Pinckard; Committee on Membership, Drs. William H. Wilder, C. D. Wescott, and Lyman Ware. Dr. Pinckard presented a brief history of the Society from the time of its organization to the present. Dr. A. E. Bulsom, Jr., of Fort Wayne, Ind., read a paper on gonorrheal ophthalmia, with complications, in which he reported several interesting cases.

Garbage Disposal.—The question of how Chicago shall dispose of its hundreds of tons of garbage gathered daily will soon come up for consideration and will come before the Council for action when the municipal cleanliness ordinance is reported back from the Judiciary Committee with its recommendations. As to garbage, there is only one thing to be done. The city must stop the present disgraceful, wasteful way of disposing of its refuse by carting it to pits or dumping-grounds. Such a way of getting rid of the daily *débris* of a great city is discreditable to intelligence and an offense and menace to public health and decency, to say nothing of esthetic considerations.

Enterostomy in Acute Intestinal Obstruction.—In a paper on this subject, read before the Chicago Medical Society, January 9th, Dr. E. J. Senn emphasized the following points (1) The value of temporary enterostomy in acute intestinal obstruction in selected cases, especially when facilities are not favorable for a laparotomy, and when the patient's condition does not warrant such an operation. (2) Enterostomy is a simple operation, requiring ordinary skill, while laparotomy with radical treatment of the obstruction is very critical. (3) The opening in the intestine should not exceed one-half inch in length, parallel with the axis of the bowel, thereby readily closing after its purpose has been fulfilled. If the obstruction persists after enterostomy, a radical operation can be performed at a later date, when the symptoms have passed away.

Indicanuria and Oxaluria and Gastro-Intestinal Fermentation.—Dr. John A. Wesener read a paper on this subject at the same meeting in which he drew the following conclusions: (1) Traces of oxalates are found normally in the urine, taken in with the food. (2) Oxalate crystals usually denote gastro-intestinal fermentation. Food rich in same must be excluded. (3) Abundance of oxalate crystals does not signify a high percentage of oxalic acid. (4) Indican is usually associated with oxalate crystals. (5) The symptoms of oxalic-acid diathesis, associated with indicanuria, are not due to the oxalic acid nor to the indol, but to other products formed in the process of fermentation. (6) In certain disturbances of the gastro-intestinal tract due to excess of hydrochloric acid, or to excess of fatty acids, indican and oxalic acid are increased. (7) Hyperacidity on a meat diet produces putrefaction.

Medical Inspection of Schools.—Fifty medical examiners, who have been off duty a month, were sent out to the public schools to-day by order of President Harris of the Board of Education. Bulletins were hastily posted to the principals of the city schools notifying them that inspection had been resumed and that they would be expected to furnish lists each day of pupils who have been absent four days on account of sickness. The lists are to be placed in the hands of the truant officers, who will make immediate investigation of the cases and report to the medical inspectors. The action was taken on the advice of Commissioner of Health Reynolds, who asked for assistance from the Board of Education in averting an epidemic of contagious diseases. The prevalence

of influenza and the fear of small-pox led the Department of Public Health to notify the Board that strenuous efforts are necessary to prevent spread of disease. A schedule has been arranged by which emergency calls may be answered at half an hour's notice, and principals have been notified to report at once any cases in which there is a suspicion of contagious disease. It is expected that a general vaccination of school-children will be ordered, and principals and medical examiners have been instructed to give the city examiners all the assistance in their power.

Joint Meeting of Physicians and Pharmacists.—At a recent joint meeting of physicians and druggists of this State, the following report was submitted and adopted: Pharmacists and those in their employ should positively refuse to prescribe for customers except in cases of urgent emergency. Any person shall be regarded as practising medicine who shall treat or profess to treat or prescribe for any physical ailment or any physical injury to or deformity of another. The law gives to pharmacists no right or authority to diagnose diseases and prescribe medicine therefor, which privilege belongs alone to physicians. Physicians should carry with them or supply to patients emergency remedies only. The substitution of one article for another or one make of an article for another in a physician's prescription, without the physician's consent, is condemned as a most reprehensible practice. Whenever a physician, for any reason, objects to the refilling or copying of his prescription, he should plainly indicate his wishes on the prescription. Pharmacists should refuse to refill a prescription or give copies of them when so instructed by the prescriber. Copies should not be placed upon containers unless ordered to be placed thereon by the prescriber. Physicians prescribing poisonous substances should add such directions as will indicate the use for which they are intended. When unusual doses are prescribed, pains should be taken to indicate to the pharmacist that the quantity prescribed is understood. In case of a suspected error or substitution by a pharmacist in the compounding of prescriptions, physicians should always satisfy themselves by conferring with the pharmacist, as to the true state of affairs, and in no case should the pharmacist be condemned by the physician, or the physician by the pharmacist, either to the patient and family, or in the press without previous careful investigation. Whenever there is a doubt in the mind of the pharmacist as to the correctness of the physician's prescription or directions, he should invariably confer with the physician in order to avoid possible mistakes or unpleasantness, and should not attempt to make any changes without such conferences. Pharmacists should never discuss physicians' prescriptions with customers, nor disclose the composition thereof to them.

GENERAL.

Carmichael Prize of the Royal College of Surgeons, Ireland.—This prize, valued at $600, has just been awarded to Mr. H. Nelson Hardy, F.R.C.S., for an essay dealing with the state of physic, surgery and pharmacy in the United Kingdom. (*Brit. Med. Jour.*)

Physician's Gift to a Hospital.—Dr. William W. Lesley, who died in Philadelphia recently, bequeathed $11,000 to the Delaware Hospital in Wilmington for the support of two free beds.

Jersey Towns Scourged.—Southern New Jersey, especially that section comprising the counties of Atlantic, Cumberland and Cape May, is reported as being ravaged by epidemics of scarlet fever and diphtheria.

Compulsory Vaccination in Kansas City.—Physicians, carrying on the crusade of compulsory vaccination begun recently, January 10th started a house-to-house canvass, vaccinating every one who could not display a good scar.

Yellow Fever.—The American Commission, under the superintendence of Dr. Reed, which has been making experiments at Quemados as to the propagation of the yellow-fever germs by the mosquito, say that they have obtained extremely satisfactory results. Dr. Reed says the experiments show that there is no contagion from an infected person or from infected clothing, but that the mosquitoes alone are responsible for the spread of the disease. Confirmation from other sources is needed, however, to establish this truth.

A Western Medical Organization.—A Pacific medical association is about to be organized. The plan is to have San Francisco the center of a Western medical field, embracing Washington, Oregon, Idaho, Montana, Utah, Nevada, Arizona, California, Alaska, British Columbia, the Hawaiian Islands, the Philippine archipelago, and other islands of the Pacific, the western part of Mexico and of the Central American republics, and possibly the empire of Japan. A preliminary meeting of the most prominent physicians interested in this movement will be held in this city on Saturday evening.

Small-Pox in Galveston.—The small-pox situation in Galveston is alarming, and Dr. Wilkinson, City Health Physician, says he cannot find words strong enough to urge the people of Galveston to be vaccinated. There are at present in the detention camp about twenty patients, three new cases being recently sent there. In the city there are about a dozen well-developed cases that are isolated and guarded. Dr. Wilkinson says the disease was brought to Galveston by the influx of a large number of country negroes who were drawn here by the prospect of earning high wages.

Adulterated Foods in America.—Adulteration of food with chemicals has never been more largely practised and was never more dangerous to the American public than at the present time, according to Prof. H. W. Wiley, chief chemist of the Department of Agriculture, whose paper on "The Legal and Medical Aspect of Food Adulteration," opened a discussion on that subject at a meeting of the Society of Medical Jurisprudence held recently.

Obituary.—Dr. Henry Foster, founder of the sanitarium at Clifton Springs, N. Y., died suddenly January 15th of heart disease. He was in his eightieth year.

Dr. Lucius J. W. Lee died on Tuesday at his home, 655 Quincy Street, Brooklyn, in his sixty-fifth year. He was attached to the Douglas Hospital in Washington, D. C., during the Civil War. He leaves a widow and an adopted daughter.

Dr. Thomas Brown Wheeler, a physician of Montreal, died suddenly in the Murray Hill Hotel last week of apoplexy.

Woman's Hospital.—Dr. P. F. Chambers has been appointed attending surgeon *vice* Dr. Thomas Addis Emmet, resigned.

CORRESPONDENCE.

CRUSADE AGAINST UNLICENSED PRACTITIONERS.

To the Editor of the MEDICAL NEWS:

DEAR SIR: The medical laws of the State of New York provide that, before one can practice medicine, a certificate of proficiency shall be obtained from the Regents of the University of the State, which is given only after a satisfactory examination. The purpose of this law is to protect the people from incompetent practitioners of medicine, and, in so far as the medical profession is concerned, this purpose is accomplished.

There are, however, many irregular practitioners who practice in open defiance of this law, apparently without molestation. This is an incentive to irregular methods, and can only be to the disadvantage of the community at large.

It is the purpose of the Medical Society of the County of New York to begin an active crusade against these unlicensed, and therefore illegal and incompetent practitioners, and we ask the cooperation of the profession and the public generally.

Any information concerning unlicensed practitioners will be gratefully received by the Board of Censors and the counsel of the Society, and will be considered confidential when requested.

Communications can be addressed to the members of the Board of Censors or to the counsel.

FRANK VAN FLEET, M.D., *Chairman*,
63 East 79th Street.

HENRY S. STEARNS, M.D., *Secretary*,
45 West 58th Street.

New York, January 10, 1901.

SUPRARENAL CAPSULE IN ORGANIC HEART-DISEASE.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I intend to publish a second paper on the use of the suprarenal capsule in organic heart-disease. Will you kindly ask the readers of your journal to send me the reports of their cases as follows: (1) The condition of the heart and pulse and pulse-rate. (2) The effect on the heart and pulse and pulse-rate within ten minutes after the suprarenal powder, three grains, is chewed and swallowed without water, by the patient.

SAMUEL FLOERSHEIM, M.D.

New York, January 15, 1901.

OUR LONDON LETTER.

[From Our London Correspondent.]

LONDON, January 5, 1901.

DECLINE OF THE OUTBREAK OF ARSENICAL NEURITIS FROM BEER-DRINKING—LORD LISTER'S ADDRESS TO THE ROYAL SOCIETY ON THE PATHOLOGY OF MALARIA—THE PREVENTION OF MALARIA IN LAGOS—AN ANTIMOSQUITO GOVERNOR.

As might have been expected the discovery that the outbreak of peripheral neuritis in Manchester and the surrounding district was due to drinking beer contaminated with arsenic has been rapidly followed by diminution of the number of cases. One result of the scare produced by the outbreak is that the numerous analyses of beer have brought to light the curious fact that arsenic may be found in samples prepared entirely from malt and not from the brewing sugars to which the peripheral neuritis has been traced, but in such beer arsenic is present in much too minute a quantity to be noxious. The arsenic has been found in the malt. It is supposed to be due to the coal used in kilning and drying, which contains an infinitesimal amount of arsenic. A number of inquests have been held and the juries have returned verdicts of death from arsenical poisoning.

Lord Lister's address to the Royal Society on the pathology of malaria which he delivered on the occasion of retiring from the presidential chair was a remarkable production in more senses than one. First, as a lucid exposition of what is now something more than the mosquito-theory—a wonderful discovery of vast importance to the human race—nothing could have been better. Second, that a man who has now reached advanced years, whose life-work has long ago been done, should show complete mastery of one of the latest and most intricate problems of pathology and one having no connection whatever with his own work, was astonishing.

The deadly colony of Lagos now boasts of an antimosquito governor. Malaria is the most critical matter in the white man's life there. Every government official after twelve months' duty has to have six months' leave of absence in England to recuperate, that is, if he is still alive, for none escape the scourge. Whilst on duty he is on an average laid aside for three months. Thus in every eighteen months he does nine months' work, the remaining nine being taken up in illness and convalescence. According to the governor, Sir William Macgregor, who is both a scientist and a medical man, Lagos "was designed by Nature as an ideal breeding-ground for the mosquito and has been extensively improved for this purpose by man." As the native malarial patient will supply the mosquito with

unlimited germs, to stamp out the disease seems impossible, but he hopes to minimize it. First, he will personally inspect every town and village on the whole length of the railway line. Wherever he finds a place where the mosquitoes can breed—depressions in the ground where the rain can form pools, unprotected cisterns, uncovered rain-water pipes, water-butts without lids, etc., he will in each case give specific instructions how it is to be dealt with. At the end of a given time he will make a second visit to see that his instructions have been carried out. To keep the mosquitoes out of houses, Sir William is getting an expert chemist to prepare a form of fumigating cone from chrysanthemum seed, the smoke of which stupefies mosquitoes. At present the seed is grown in Hungary and pastilles are manufactured from it in Italy. The governor intends to grow it on the spot. The pastilles will be sold almost at cost price to the natives. Then Sir William is taking out with him a master carpenter, a master tinsmith and a large supply of wire-gauze. He will provide every white official with at least one mosquito-proof room for use after dark. He will also institute a number of mosquito-proof wards in the infirmaries. At the same time natives will be apprenticed to the carpenter and the tinsmith and will learn how to make and fit mosquito doors and shutters and how to make wire-gauze. All the medical men in the colony will lecture on mosquitoes and malaria to the school-teachers, who in their turn will instruct the natives in the ordinary school curriculum.

TRANSACTIONS OF FOREIGN SOCIETIES.

INFECTIOUS ANGIOCHOLITIS—PRIMARY TRACHEAL SUTURE—ARTHROTOMY FOR OLD LUXATION—FRACTURES OF THE LOWER JAW—RESECTION OF THE ELBOW—RESECTION OF THE HIP—RESULTS OF LORENZ'S REDUCTION OF CONGENITAL DISLOCATION OF THE HIP—SERUMTHERAPY AND TUMORS—MASSOTHERAPY IN PHLEBITIS—MULTIPLE PUERPERAL PHLEBITIS AND MORTAL INFECTION—PREPHLEBITIC, PHLEBITIC AND POSTPHLEBITIC PUERPERAL SYMPTOMS—PALPEBRAL EDEMA—APHASIA AFTER TYPHOID FEVER—PRIMITIVE PROGRESSIVE MYOPATHY.

Michaux, at the Société de Chirurgie de Paris, November 21st, 1900, gave account of a case of angiocholitis under the care of Pauchet (Amiens). The onset was subacute and accompanied cirrhosis. January 25th last a cholecystostomy was performed and cure followed without incident. Seven months later at the request of the patient a cholecystectomy was performed after the subserous method of Doyen. To Michaux the presence of a cirrhosis did not seem to be established by all the conditions in the operator's report. Since in three bacteriological examinations the bacillus coli communis was formed each time, he thought that the case was an ordinary infectious angiocholitis of mild degree. Nevertheless the patient received very great benefit from the operation. The bacilli in the bile discharged through the fistula decreased and finally disappeared. It was at this time that Pauchet did the secondary operation. It would have been better judgment to have permitted the sinus to close itself. Michaux has had in his own experience a thirty-four-year-old man who gave symptoms of infectious angiocholitis with jaundice. Exploratory laparotomy revealed considerable enlargement of the liver and lymphatic glands. The diagnosis was confirmed and a kind of massage carried out on the bladder and ducts. This, without cholecystotomy, completely cured the patient. Segond, Routeer and Quénu have had similar cases. In the presence of a true hypertrophic cirrhosis he had seen marked benefit follow a cholecystotomy, but only up to a certain point. The patient had very recently reported that he still suffers, though improved. When there is infectious angiocholitis, he rejects an anastomosis between the gall-bladder and the intestines, but regards a fistula opening upon the skin as preferable. Hartmann regarded the cholecystostomy in the case of Pauchet as unnecessary, because in the absence of jaundice, probably no obstruction to the bile-flow was present. Therefore, such cases get well after simple exploration, owing no doubt to the rest in bed and the post-operative diet and regimen.

Routier, alluding to his case mentioned by Michaux, said the woman gave all the signs of obstruction of the common bile-duct, was treated solely by massage of the passages which probably dislodged a mass of mucus and established the free flow of bile into the intestine and cure.

Lejars at the sitting of December 5th continued the subject by reporting a case with all the symptoms of biliary calculi with jaundice. No stones were found on exploration, but a cholecystostomy was done. The exposed liver had many appearances of cirrhosis, which were diminished or absent when the fistula was closed at a secondary operation. Michaux added that for clinical purposes it would be well to know the subsequent history of these cases of infectious angiocholitis in order to determine the character of the liver lesion. Quénu stated that he had followed many of his patients long and closely enough to be certain of their permanent cure. In one patient the lesion was a perihepatitis complicating a large cirrhosis. Nine years afterward the general condition of the patient was very satisfactory, although the size of the liver had not decreased.

Picqué, at the meeting of November 21st, reported for Mesnard a recovery after wound and primary suture of the trachea. The man had attempted suicide and with a razor had made a ragged cut through several of the rings. With catgut a kind of trellis was made, apposing the edges of the tracheal wound. The method succeeded admirably.

Nélaton, December 5th, contributed two cases of arthrotomy of the shoulder for old dislocation. Although the procedure was carried out under favorable conditions and the healing was satisfactory, the functional outcome was far from good. This corresponds with the report of Ricard at a previous

meeting of one case and with the experience of most authors in literature. On the other hand, Nélaton has treated twelve or more such old cases without the opening of the joint and the function was finally very excellent.

Delbet said that during the summer a patient in whom no lasting reduction of a shoulder dislocation could be done, demanded and was refused by him open restoration of the joint. Another operator consented, but finally had to resect the head in the interests of function. Ricard noted that since his previous report his patient had much improved, therefore he felt the operation should not be entirely abandoned.

Martin, at the Société de Chirurgie de Lyon, July 12th, referred to his treatise of 1887 on fractures of the lower jaw and the apparatus he then described for treating them, and emphasized the advantages of managing these cases with the mouth open. He now abandons all external splints except a molded rubber one. The posterior fragment is the one which gives difficulty by being hard to depress and reduce. The shorter this fragment is the greater its tendency to displacement. When the jaw is open the posterior part naturally is depressed and when fractured a very good reduction of the fragments is almost spontaneous. Retention in this position is then alone needed, for instance, with a wedge of wood or of some other material, which acting like a splint fixes the rear fragment while the front one is apposed carefully to it and held in position by the rubber external molded splint, which is best arranged to include the chin too. It is necessary to wear this combination until the first steps of union are accomplished. As a rule, the alignment of the fragments is most excellent. Massage may then be gently applied. Results are in proportion to the care of the primary reduction. The method has been continuously employed by the author for the past ten years, and always with satisfaction and success, in about forty cases. The method has the disadvantage of trying the patient a great deal and cannot therefore be used unless the disposition will tolerate it. When there is comminution of the bone, some form of internal splint must be applied to prevent deformity.

Ollier exhibited a patient in whom gonorrheal synovitis had produced ankylosis of the elbow. The first treatment was forcible breaking-up of the adhesions, the prognosis of which was stated as doubtful in advance. At its ultimate failure, the patient demanded radical cure. The joint was freely opened and with the scissors attempt was made to divide all the hindering bands. Their extent made resection necessary, which, after free laying open of the soft parts, was done until free movements were obtained. Recovery was prompt and the result excellent, perfect flexion, a little hyperextension which will probably correct itself, and some lateral mobility which as the soft parts unite more with the condyles will tend to disappear. The final result will probably be very flattering. The point emphasized is wide exposure of the joint by freeing the soft parts all around the joint. Ollier also presented a case of resection of the hip, in which choice had been between that and a cuneiform cervical section, for coxalgia and ankylosis with pain. The former was desided upon as well, as there was still an area of inflammation. At first the neck was sawn through, and then the head was removed. A most excellent result ensued, with perfect ankylosis. Ordinarily mere division of the neck or the cuneiform section would have been the choice, but the element of pain rendered resection advisable.

Nore-Josserand, at the next meeting, showed a specimen from a little girl, four and a half years old, treated for congenital dislocation of the hip by the reduction of Lorenz. Death occurred during an attack of diphtheria. The muscles of the dissection were all normal as to color, consistency, nutrition and direction, being only a little the less heavy on the diseased side. The diaphysis of the femur was somewhat thin, the neck short and the head overdeveloped. The condyloid cavity was too shallow, but withal accommodated the head very well. The capsule was practically normal, even in its auxiliary ligaments. As a whole the joint had the appearance of being somewhat compressed, but was a very good articulation, except for the absence of the round ligament.

Le Dentu, at the Académie de Médicine, November 27th, reiterated the conservative findings recently enunciated by Lucas-Championnière and Berger during the last session as to the anticellular serumtherapy of Wlaïew in the treatment of malign tumors. Up to the present this method has given in the hands of surgeons at the best only uncertain results. Therein it is comparable to the serum from the streptococci of erysipelas, either free or mixed with that of the micrococcus prodigiosus, also the serum of animals inoculated with the juice and with the pulp of such tumors. The limited, though real efficacy of such inoculation seems to depend upon some temporary effect upon the elements occurring in common among all tumors as widely different as the sarcomata and the epitheliomata. Such common elements are, of course, at the present time not definitely differentiated. Or, again, such elements might be accessory and hence, though really and deeply affected, have no influence upon the essence of the tumor and therefore no cure results. It is likely that the best method of treating these malign invaders is by early wide extirpation. The earlier the diagnosis and the excision the better the result. Although absolute cure may not be obtainable, the general condition of the patient is benefited and alleviation is gained.

Hirtz, at the Société Médicale des Hopitaux, November 23d, said that he differs somewhat from Vaquez who at the last meeting stated that he employs massage in phlebitis about twenty days after the onset, provided all the palpable veins have ceased to be tender, all pyrexia has vanished and all edema is frankly disappearing. For his own patients he prefers to wait longer, say at least four or five weeks after the onset, and in the presence of the same favoring factors. In many cases of rheumatic, goutly and varicose phlebitis he delays active interference still longer.

QUELMÈ (Paou) presented notes on a case of postpartum phlebitis in a multipara, appearing nine days after delivery, affecting at the onset only the two lower extremities, later extending to both upper extremities, and having pulmonary embolism with a pneumonia. In succession both eyelids became edematous, perhaps by thrombosis of the ophthalmic veins. High fever interrupted by chills persisted. Later weakness of the heart, dryness of the tongue, cerebral manifestations, and, as a final development, a purulent pemphigus of the lower extremities. Anuria, without albuminuria preceding it, appeared just before death.

STAFFER offered the account of a puerperal case in which for five days after delivery a subfebrile state persisted; after ten or twelve days of apyrexia a phlebitis of one lower extremity appeared with some fever. Soon the other lower, later one of the upper members became affected without edema. After fifteen days of this fever, the temperature suddenly rose to 41° C. and attacks of intense cephalalgia, with pain and spasms in the muscles, appeared. Warm baths relieved the condition and after about two weeks cure was established.

GAILLARD, at the meeting of November 30th, narrated the histories of two cases of acute idiopathic palpebral edema in children with arthritic antecedents. The first concerned a female four and one-half years old, who, while at the seashore, was overtaken with edema of one eyelid without any lesion of the eyeball or injection of the conjunctiva. It attained large proportions, persisted twenty-four to thirty-six hours, disappeared entirely and recurred after six weeks. There were in all eight relapses, first on the right, then on the left side. The second patient, also female, three and one-half years old, was after an attack of rheumatism left with a hydrarthrosis of the right knee, without fever. Five days later she had a papillary erythema of both lower extremities; on the morning of the seventh day the lids of the right eye were closed by an enormous edema, which also affected the left eye to a less degree. There was no conjunctivitis and no fever. In two days all this edema disappeared, but there remained purpura in the buttocks and bases of the thighs. Twelve days after their appearance all these signs had disappeared.

BARIÉ said that in at least one of these patients there was an eruption localized in the lids accompanying the erythema papulosa, attributable no doubt to digestive disturbances. Recently he had a patient who presented much swelling of the face during convalescence from a polymorphic erythema. Beside a rubeolic eruption of the forearms and scarlatiniform of the back and trunk, the patient had urticaria on the trunk and face. Notwithstanding the great variety of these cutaneous lesions, they were all probably due to an intestinal intoxication of some obscure type.

DR CASTEL said that simple localized urticaria would explain the characters of the phenomenon very well and had in support of it the fact that in one individual the disease began at the seashore.

SIREDEY showed a youth recovered from a severe attack of typhoid fever with disturbances of speech and motion as sequelæ. The motor lesions affected the lower extremities, especially the left, were accompanied by increased patellar reflexes and the toe affections of Babinski. The speech was of the scanning type so often seen in multiple sclerosis. Although intention tremors and nystagmus were absent, the author felt that this was probably the patient's disease. Hysteria was certainly not present.

BARBIER reported an observation of a girl eleven years, the subject of a primitive progressive myopathy, apparently originated in her infancy in the lower extremities; later the upper extremities, the trunk and the face became involved. There was a real generalized atrophy, but more or less pronounced according to the region. The buttocks and the gastrocnemii were with a few others really increased in volume. Notwithstanding their enlargement they were manifestly feeble. The gait was waddling, with the feet wide apart. She had very great difficulty in assuming the erect from the sitting or the recumbent position. The hereditary taint was direct, as a sister and a first cousin also had the disease.

SOCIETY PROCEEDINGS.

THE SOCIETY OF THE ALUMNI OF THE CITY (CHARITY) HOSPITAL.

Stated Meeting, Held October 10, 1900.

The President, W. L. Baner, M.D., in the Chair.

Acquired Heart-Disease in a Child Three Years Old.—This paper was read by Dr. Francis E. Butler. The case is interesting from the fact that it is one of acquired heart-disease with very extensive lesions. Such an extensive cardiac involvement at this early age is due, as a rule, to some congenital defect in the heart, either in the septum or pulmonic valves. When the condition was first manifest the boy was three years and six months old. How long before this the lesion began, and whether it was a rapid involvement or an insidious condition so common in children, was not definite. There was apparently no joint lesions. The family history is as follows: His mother had an attack of articular rheumatism while she was nursing him. His father had a brother who suffered from rheumatism. He has one sister and two brothers in good health, who gave no history or symptoms of rheumatism. One sister died of meningitis several years ago. He was nursed for a year and then fed on anything. Was a strong healthy child up to about a year ago, when he was admitted to the Hospital for Ruptured and Crippled for operation on bow legs. Osteotomy was done. He contracted whooping-cough in the hospital and was sent home. Soon after measles developed. He recovered from the measles and whooping-cough and soon regained strength. He was apparently well

for about four months. In June, 1900, the mother and brother noticed that on the slightest exertion he became short of breath, had great difficulty in breathing; he was pale and anemic, not eating much, very irritable, and could not sleep at night. Apparently there had been no history of pain, either in the joints or extremities. He was taken to the Outdoor Department of the Hospital for Ruptured and Crippled and the mother was told that the child had rheumatism. She then took him to the French Hospital; not improving there, he was brought to the Outdoor Department of St. Vincent's Hospital on July 28th, at which time the following points were learned.

Up to about nine weeks ago the child had been in perfect health, when he began to have great difficulty in breathing, lost weight rapidly, became pale, listless, irritable; when he walked or played a little he became short of breath, sighed and grunted, put his hand over precardial region, looked anxious and distressed. An examination at that time showed the pulse 144, respiration 70 and labored. He had a strong heaving pulsation all over the cardiac region. There was marked epigastric pulsation. The apex beat was forcible in the fifth intercostal space, almost under the sixth rib, about one inch outside the left nipple line. There was a distinct thrill and fremitus about the apex of the heart and ensiform cartilage. On ausculation, there was a loud, harsh, blowing murmur, apparently systolic and diastolic, strongest at the apex and transmitted to axilla and back, in fact, it was heard all over the chest, obscuring all other sounds of the heart except the pulmonic second sound in the second intercostal space, which was markedly accentuated. There were a few râles in the chest and a frequent, irritating cough. His liver was enlarged about three-quarters of an inch below the free border of the ribs. He was sent home, kept in bed as quiet as possible and fed on eggs and milk, meats and liquid peptonoids, about a dram every three hours.

On August 4th he was brought to the Dispensary. His brother said he complained of pain in the cardiac region, frequently put both hands over the cardiac area. There were a few pleuropericardial friction sounds. The heart condition seemed about the same at that time. He was given Fowler's solution (♏ iij, t. i. d.) and liquid peptonoids. About two weeks after that he reported at the Dispensary again and was doing much better; he did not complain of pain, dyspnea was not so marked; he ate better, the heart sounds seemed about the same and cough was less. On September 1st the general condition was much improved. He was able to play about and walk easily and breathe fairly well. He was given Fowler's solution (♏ v. t. i. d.) and liquid peptonoids; pulse 120, respiration 40. In two weeks he was much improved, could walk down three flights of stairs, but would not try to walk up, insisted upon being carried. He had lost the anxious expression of face.

He has been doing pretty well up to the present time, not so well last week, probably due to the damp, heavy weather, which seemed to depress him. He had a great deal of difficulty in breathing: his dyspnea seemed more marked. He has a very loose cough. The heart sounds seem much improved, more localized at the apex, and the sounds of the aortic valves can be heard distinctly; the murmur is still heard over the whole chest; pulsation and heaving of precardium less forcible; apex beat still outside the nipple line in the fifth space; pulse 128, respiration 40.

Dr. William L. Stowell said that he had a case somewhat similar in a child four years old, with acute articular rheumatism and endocarditis. As to the treatment of these cases, cardiac stimulants had very little effect. Nearly all the benefit was gotten by tonic treatment. He had seen cases in which the condition was acquired. Children often outgrow these diseases. If the lesions were not marked, degeneration did not take place readily in the child. They outgrew a great many physical defects that an adult could not get over. In the case presented the regurgitation was considerable, and it would be remarkable if it should improve much; but where the lesion was less extensive and there was less dilatation, there was a good chance of their living to an average age. There were multitudes of people living who had had heart disease for many years. The earlier these cases were detected and the more successfully the patients could be nourished as they grew up, the more certainty of their overcoming the disease.

Dr. Walter L. Carr said this was one of the cases that were always of great interest. The condition of the heart was one that made the origin of the trouble doubtful. Many of these children with valvular disease have had rheumatism, and of that type which so often occurs in childhood, where there was no evidence of acute pain, frequently no symptoms of any joint trouble. There might be a family history, a little uncertainty as to so-called growing pains, or often no history at all. In this particular case there was some doubt as to the origin, in connection with the fact that the child had had pertussis and measles. There may have been symptoms of endocarditis at that time, as pertussis and measles are sometimes followed by myocarditis or endocarditis. It was hard to say much about the condition of the heart, that is, its actual strength. Very often there was degeneration of the heart-muscle, then again the child would get over such a condition; and while the prognosis was grave, such cases did recuperate, and with careful watching passed beyond puberty, to a comparatively old age. Sometimes we were skeptical about the recovery of these cases, where there was no evidence of it, no great hypertrophy, nor sign of interference with the circulation. The difficulty was to treat these cases properly, to allow the heart-muscle to regain its strength and for the general circulation to be carried on properly. These patients need rest, but if they were dispensary cases, medicine was often given, and

sometimes medicines which they did not need. Very frequently it was digitalis, which a great many children were better without. More frequently they needed something to act on the liver or to relieve the general systemic circulation. In private practice in such a case the child should be kept quiet in bed; then directions about having the bowels regular and the care of the digestion, so that the stomach and intestines were not distended after eating, should be given; so that the diaphragm would not be pushed up, the heart displaced, and the circulation made uneven from mechanical conditions. If the heart-action was weak, digitalis might be used; but more cases would be better without digitalis than with it. The heart-action would fall ten, fifteen and twenty beats if the child were kept quiet. Symptomatic medicines were often called for to relieve pain, stimulating cough mixtures for the bronchial membrane, and preparations of alcohol for a general tonic effect; but it was not thought that any child would do well with the indiscriminate use of alcohol, any more than the indiscriminate use of digitalis. One mistake was often made, naturally, that if the murmur was loud, the child was kept under treatment; but if it was a soft murmur, not well heard, the physician often thought the child was doing well. The low-pitched, soft murmur was sometimes due to the change in the heart-wall, and the child might then need the very digitalis and alcohol which were being discontinued. The kidneys should be carefully watched. The urine was sometimes albuminous, and at times showed casts. The whole matter of the care of these cases was primarily that of rest, which would, more than anything else, lessen the degeneration of the heart-muscle; and by slowing the heart-action certainly give it a chance to regain strength.

Dr. Adolph Rupp said he wished to ask only a few questions. Why call such cases in particular acquired? Everything after birth is acquired. With reference to the etiology, as regards rheumatic influences, it was often difficult to say whether so-called rheumatic affections are really rheumatic. Physiological chemists and bacteriologists are changing one's conceptions in these matters very much. Within the last two months he had treated two children who had had chronic diarrhea for weeks and months. After recovery from the diarrhea they had joint affections, and then developed cardiac murmurs and albuminuria. He asked whether the urine had been examined in the case presented.

Dr. Butler said he examined the urine twice and did not find albumin. He did not examine it with reference to casts.

Dr. R. C. Newton mentioned a case that he saw in consultation about five or six years ago. The boy had a similar history and lived to be about eight years old, when he was taken with pneumonia which was fatal. He secured the heart and brought it to the Section in Medicine at the Academy, where some of those present may have seen it. The lesion turned out on examination to be a case of perforate ductus arteriosus. On auscultation the heart sounds were very much like those in Dr. Butler's case. There was a loud double murmur, and a great deal of hypertrophy. The boy had a pale, pasty complexion and little muscular development.

Perforation Following Pink-Eye.—Dr. Geo. McAuliffe showed this case, not because it was particularly interesting or unusual, except that it was the consequence of pink-eye. No doubt everybody has treated a great many cases of pink-eye this year, and had gotten to look on it as fairly innocuous after antiseptic treatment was instituted. This boy had an attack of pink-eye about three weeks previously. The perforation of the cornea took place about a week ago. He was not particularly warned about his eye, was told to use the combination of bichloride solution, 1-5000, and boric acid. Further than that he did not give it any attention and did not think it wise to come back and see about his eye. The consequences were only too obvious. It illustrated the need of careful examination and watchfulness in contagious ophthalmias. The prognosis of pink-eye in itself was good. He had examined about 100 cases in the Harlem Hospital Dispensary and inside of four days the inflammation would be near an end. This was apparently an uncomplicated case of pink-eye; it had the ordinary treatment and was dismissed with twenty or thirty cases. The patient did not come back until the perforation, preceded by scarcely any symptoms, had taken place. It showed how necessary it was to watch contagious inflammations.

Skiagraph of a Case of Pneumonic Osteo-Arthropathy.—Dr. Newton showed a skiagraph of the right hand of this case. The disease had been described by Marie and had been alluded to by Osler. The ends of the fingers and toes were involved and the facial bones spared. In Marie's opinion the disease is due to a latent or very low form of tuberculosis. The patient came into the hospital suffering from a large axillary abscess, which was evacuated in the usual way, washed out with bichloride and drained. It did not recover during the speaker's service. It being thought that the abscess had not been cleaned out properly, it was scraped out, opened up freely, and two or three more drainage tubes put in, but the wound did not heal. It was again opened and scraped out, but the abscess only partly healed. Having this large axillary abscess and being well bandaged up, a thorough examination of the man's heart and lungs could not be made, but on partial examination there seemed to be nothing wrong with the heart or lungs. The man was a Hungarian, a farm laborer, thirty-four years of age, and of fair intelligence. He said that his brother and father both had these peculiar fingers and toes and broad nails. He declared that his nails had always been this shape. He has had three children of his own, two of whom died early. The survivor has the same sort of fingers.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.
SECTION ON SURGERY.

Stated Meeting, Held December 10, 1900.

Charles N. Dowd, M.D., Chairman.

Total Ureterectomy.—Dr. Willy Meyer presented a patient from whom the left ureter had been removed. The patient is a man of thirty-seven years of age, who suffered from pyelonephritis for several years and who four years ago had a left-sided nephrectomy performed. His general condition improved after the operation. He gained in weight and his febrile symptoms entirely remitted. The local symptoms were not improved, however, and he suffered from pain in the left side and from vesical irritation. There was frequent and imperative urination. Drainage through the perineum was suggested for this, and as long as the perineal opening remained his condition seemed improved, but as soon as it closed the old symptoms recurred. Washing the bladder was then done for a long time, but without any permanent benefit. Owing to the presence of a valve in the urethra, a steel instrument could not be passed. Cystoscopy was unavailable and it was impossible to collect the urine from the supposedly-healthy kidney and the secretion, if any, from the left ureter by means of urethral catheterization.

Diagnostic and Operative Technic.—Under these circumstances the following plan of determining the local condition was devised. The urine was passed and put aside; deep massage was then done over the region of the left ureter, and the urine was passed a second time. The second urine contained an amount of foul-smelling material that was not present in the first urine, and this showed that a septic infective process was at work in the ureter of the side on which nephrectomy had been done. Ureterectomy was decided on and the incision adopted was that suggested by Dr. James Israel of Berlin. The incision was carried parallel to the twelfth rib until the tip of the eleventh rib was reached. This wound was prolonged downward to the middle of Poupart's ligament and from there carried over to the median line. The ureter in this case was extremely hard to find because of the absence of the usual anatomical landmarks. The ureter was found buried in a mass of inflammatory tissue on the left side and was excised only after the most patient dissection.

Examination of Ureter.—This case emphasizes very forcibly the lesson that whenever nephrectomy is done, if the ureter is not removed with the kidney the operator should determine positively that there is no serious pathological process in it. In every case bougies should be passed down to the bladder to be sure that the ureter is free. Nephrectomy has failed in a number of cases to give the expected relief, because some pathological condition of the ureter remained unrecognized. Sometimes the stricture will be found in the ureter at its entrance into the bladder.

Abnormal Appendicitis.—Dr. John Rogers presented three cases of peculiarities in appendicitis. In the first patient, a boy of thirteen, an ordinary appendiceal abscess was opened and a pint of fetid pus evacuated. The boy convalesced normally for ten days and then after having eaten some candy developed acute symptoms on the left side. There was pain, localized tenderness and vomiting that seemed to point to intestinal obstruction. A diagnosis of invagination of the intestine was made and an operation performed. Incision led to the evacuation of a pint of pus from this side and then the boy proceeded to get well again. Some two weeks ago afterward localized symptoms of pain and apparently of a collection of pus were noted in the epigastric region. He had been running an afternoon temperature for some days that pointed to the existence of a purulent focus. A diagnosis of abscess was made and a third incision made, this time in the epigastrium. No abscess was found, but an adhesive peritonitis existed. The intestines were found agglutinated. The abdomen was washed out, the wound closed. The patient made a good recovery. The second patient, a boy of fourteen years, when admitted to the hospital was supposed to be suffering from typhoid fever. A tumor was found in the left iliac region and there was an afternoon temperature. The condition was found to have developed after gastro-intestinal disturbance. Pain and tenderness were distinctly localized at the beginning on the left side. When young subjects suffer from acute pain following gastro-intestinal disturbance, the safest diagnosis is appendicitis. This was made in this case and an operation performed. The appendix was found to lie transversely across the abdomen, the tip of it being almost midway between the umbilicus and the anterior superior spine on the left side. The end of the organ was gangrenous and it was here that the abscess had formed.

In the third patient, a boy of six, an abscess was opened in the usual locality for the occurrence of appendiceal abscess, but the patient's condition was so bad that extensive search for the appendix was not justified. After the draining of the abscess the boy got better, but after about ten days he was given some German-seed cake, after eating which pain and tympanites developed. The temperature ran up and vomiting set in. Examination of the abdomen showed an area of dulness in the region of the gall-bladder. An incision was made over the point where the collection of pus seemed to exist and the tip of the diseased appendix was found in the middle of an abscess adherent to the first portion of the duodenum. The appendix was abnormally long.

Sponging for Peritonitis.—Dr. Berg presented a patient who had been suffering from typical appendicular symptoms. The case was not a severe one, however, the pulse being but 95 and

the temperature below 101° F. Shortly after the examination was made, intense abdominal pain developed and all the symptoms became very acute. The temperature rose to 104° F., the pulse to 130 and there was persistent vomiting. Operation was done as soon as possible, although several hours had elapsed and the pain had become so severe that the patient threatened to commit suicide. An intensely fetid peritonitis was found. The glands all over the abdominal cavity were enlarged. Pus was everywhere. The condition is described as diffuse peritonitis, not general peritonitis, because no examination of the lesser peritoneal cavity was made. The abdomen was carefully sponged out, sponges being carried well up under the liver and beneath the spleen and down into the pelvis. The reaction seemed almost marvelous. The operation was done late in the evening; the next morning the man was reading a newspaper and his temperature was 101.5° F. This is the eighth case in which Dr. Berg has used this method of sponging out for extensive peritonitis. In only one case has there been a fatal result. This took place as a consequence of an extensive abdominal phlegmon. The phlegmonous inflammation started from a stitch-abscess. Such abscesses are always a source of some danger in these cases, because, while the peritoneum seems to be perfectly capable of taking care of the infective material which may remain on it, the tissues of the abdominal walls do not prove so resistant. Four weeks after the operation the temperature in this case rose and signs of a subphrenic abscess were found. This was incised through the costal route in the axillary line. It is extremely difficult to clean out all parts of the abdominal cavity with sponges, and especially is it hard to reach the space between the liver and the diaphragm through an appendiceal incision.

Dr. Morris said that left-sided abscess is not infrequent and left-sided phlebitis sometimes occurs as a complication or sequela of appendicitis. Such abscesses are liable to develop some time after the original operation. During the height of the inflammatory reaction there exists a hyperleucocytosis which protects against infective material. Later on when the leucocytosis diminishes infective material is able to display its virulence.

Dr. Erdmann has had two cases of appendicitis in which the pain and tenderness occurred in the epigastric region and the abscess that formed was opened in this region. Dr. Erdmann asked if the pus in Dr. Berg's case had been examined bacteriologically and if the active agent in it had been found to be the bacillus coli communis. Dr. Berg replied that the bacillus coli communis had been found. Dr. Erdmann then said that the very fetid cases of peritonitis were always caused by the bacillus coli communis and that it was not a very virulent organism. He always congratulates himself in peritonitis cases when he finds that the pus within the abdominal cavity has a very fetid odor, because the prognosis is very much better in these cases.

In closing the discussion Dr. Berg said that his experience had not been like that of Dr. Erdmann and that very fetid pus often meant intense peritonitis and a bad prognosis.

Operation for Movable Kidney.—Dr. Robert T. Morris said that when operation was first suggested for movable kidney the sutures to hold the kidney in place were passed only through the capsule. Later the stitches were passed through some of the kidney parenchyma also. The inventor of the operation reported as the result of 27 operations, 15 recoveries, 4 improvements, 7 relapses and 1 death. This would be considered a poor showing at the present time. Guyon made the first suggestion for the improvement of the technic of the operation. He removed the fatty and the fibrous capsule and hoped that the plastic lymph which formed on the surface of the kidney would fix it securely. This operation fixes the kidney. Pain after the operation is, however, not unusual. At least there is a feeling of persistent discomfort which while not quite painful is often seriously annoying.

Dr. Senn suggested a further improvement in technic. He removed the kidney fat and scarified the capsule, afterward packing the wound with gauze so as to induce a throwing out of plastic lymph and a formation of connective tissue that would hold the kidney in place. Dr. Morris has used this method of Senn's in two cases with excellent results. The healing of the incision is, however, too slow in this method and this makes it unsuitable for the majority of cases. Some simpler method seemed advisable.

Capsule Fixed to Muscle.—Dr. Morris noted some years ago a suggestion to strip the fibrous capsule from the kidney over a large portion of its surface, pass the flap thus formed through a slit in the psoas muscle and stitch it there. At times the normal position of the kidney and the anatomical position of the muscles makes the quadratus lumborum more available. The advantage of this method is that no injury is done to the parenchyma of the kidney. Injury of kidney substance is inevitable where sutures are passed through the organs. The absorption of the suture always leaves a band of fibrous tissue. Such kidneys present a change in the secreting substance, sometimes even at a distance from the suture tract. A number of good observers have thought that clinically they could notice the damage done to the secretory function of the kidney. This new method is a very satisfactory one, also because it seems to give less liability to relapses than do most other methods of kidney fixation.

Effects of Movable Kidney.—Certain serious effects produced by floating kidney apart from the general symptoms that are characteristic of the condition seem worth while noting. Gallstones frequently occur in cases of floating kid-

ney as the result of the pressure on the common bile-duct and the consequent interference with secretion and drainage. In a certain number of cases it has been noticed that the pressure of the loose kidney upon the duodenum has caused distention of the stomach. This is a true dilatation from obstruction and not merely a ptosis of the stomach as the result of a general relaxation of intra-abdominal tissue. In some cases it has been noted that pressure of the displaced kidney upon the superior mesenteric vein caused congestion of the cecum and appendix and so predisposed to attacks of appendicitis. The work of Dr. Edebohls especially has called attention to this complication of floating kidney, and his observations have been confirmed by a number of other investigators in recent years. Reflex gastric symptoms are very common as a result of irritation of terminal endings of the vagus nerve. Reflexes of the heart and of the esophagus are not so well known nor so frequently recognized, but they undoubtedly occur. In a recent case under Dr. Morris's care a patient presented most of the classical symptoms of esophageal stenosis. Bougies were used by prominent clinicians to overcome the esophageal stricture. Gastro-enterostomy, with backward dilatation of the esophagus, was suggested by surgeons in Boston and New Orleans. The patient found that, if he could lie down and keep his kidney in place during the act of swallowing, his difficulty was overcome. The irritation of the terminal nerves in the kidney sometimes sends reflexes into Auerbach's and Meissner's plexus. This occasionally gives rise to intestinal symptoms and predisposes to membranous colitis. This, of course, is a disputed question, but at least one recent case of Dr. Morris's seems to show a positive connection between the two affections. The patient was a physician who before operation for kidney fixation suffered from colic and the passage of mucous stools with membranous casts every morning for several years. Frequently during the day the colic and mucomembranous stools recurred. The man had become so exhausted that he considered it absolutely necessary to give up his practice. Since the operation he has had absolutely no distress, the attacks have disappeared, there is no mucus and no membrane in the stools. He has lost all his old tired feeling and he can work all day.

Palliative Treatment.—In the majority of cases of loose kidneys operation is not needed. Operation is necessary only when all ordinary mechanical means, bandages and the like, fail to keep the kidney in place or prevent the recurrence of reflex symptoms. Some loose kidneys give absolutely no symptoms. A short time ago, Dr. Morris had under observation a young woman who is a cross-country rider. She had noticed two funny things in her abdomen that seemed unusual and moved from place to place. They had not given her the slightest symptoms, she wanted to know what they were. In a certain number of cases floating kidney is associated with general enteroptosis, that is, a relaxation of the mesenteric attachments of all the abdominal organs that allows them to sag out of place. The liver, the stomach, the spleen, and the intestines may all hang lower in the abdominal cavity than they should and produce a reflex effect on nerves, as well as functional disturbance of the various organs. Surgical treatment of this condition is not so discouraging as many people consider it to be. All of the organs may be secured in place by making folds in their respective mesenteries. This operation is reasonably successful and produces an amelioration of symptoms that makes patients feel that they are practically cured.

New Kidney Tissue.—Dr. Edebohls said that a series of experimental observations made some years ago showed that new kidney tissue forms in kidney defects. When injury of the kidney causes destruction of the secreting substance proper, the defect is first filled in by connective tissue, but this is afterward replaced by true secreting substance. Dr. Edebohls has done 200 nephrorrhaphies, each time the sutures being made to pass through kidney substance. In not a single case has there been any subsequent discomfort traceable to the placing of the sutures in this way, nor have there been any clinical symptoms of interference with kidney function. The pain sometimes noted after operation for kidney fixation is usually due to a division of the ilio-inguinal and ilioguteal nerves. These are important nerve-trunks and should be pushed aside. If from inadvertence or necessity one of them is severed, it should be sutured.

Capsule Insufficient Anchorage.—Dr. Edebohls does not think that the capsule of the kidney is ever sufficient to hold a movable organ in place. The liver presses down upon the kidney and in coughing, sneezing and the like, considerable strain is put upon the organ, which forces it from its bed unless it is well anchored. In Dr. Morris's method it is not the capsular tissue which holds the kidney in place, but the fact that the surface of the kidney is extensively denuded and that this gives rise to lymph exudation and formation of new connective tissue. Dr. Edebohls is perfectly satisfied with the method of passing sutures through the kidney substance. In all of his cases there have been only five relapses. These relapses occurred in cases operated upon seven and eight years ago, and during the last five years there have been no relapses.

Sponge Disinfection.—Dr. C. A. Elsberg presented a new and simple method of sterilizing sponges by boiling. Boiling under ordinary circumstances renders sponges hard, rough and inelastic and makes them very unabsorbent. These difficulties with sponge sterilization have caused them to be replaced very generally by gauze pads, although these are much less capable of absorption. The secret of Dr. Elsberg's method consists in the use of a solution in which

the albuminoid material of sponge is normally precipitated. The principal albuminoid constituent of sponge is spongein. This precipitates in a two-per-cent. solution of tannic acid, to which a one-per-cent. solution of potassium hydrate is added in equal parts. Sponges may be boiled in this solution any number of times and not lose any of their physical qualities. Bacteriological examination has shown that no germs exist on or in the sponges after sterilization by boiling. The sponges are first freed from calcareous material by being kept for some time in an eight-per-cent. solution of hydrochloric acid. They are then boiled on three successive days for a half-hour each day in the solution of tannic acid and potassium hydrate. This makes the sponges dark brown; they are then washed in sterile water until this color disappears. This makes a rapid, effective and inexpensive method of boiling sponges and when thus treated they may be used any number of times without danger.

Dr. Dowd said that this method fills a long-felt want in surgical technic, and that sponges treated by this method will surely be of the greatest service, as most surgeons are dissatisfied with the slight absorbent capacity of the gauze pledgets that are now in use.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held December 10, 1800.

The President, Robert F. Weir, M. D., in the Chair.

Discussion on Spinal Anesthesia.

Neurophysiological Aspect of the Subject.—Dr. J. Leonard Corning opened the discussion with this paper. He gave a brief account of the researches and experiments on animals and the human subject which led him to the discovery of the method of intraspinal cocainization now in vogue.

Spinal Analgesia in General Surgery.—This paper was read by Dr. George R. Fowler of New York. (See Medical News, Vol. 78, p. 1.)

Obstetrical and Gynecological Aspect.—Dr. Marx said that his earlier experimental cases were failures because cerebrospinal fluid did not escape. In the first case in which he got fluid he was badly frightened when the patient developed symptoms resembling locomotor ataxia; but felt relieved afterward when the woman gave birth to a child without knowing it. In all his cases since then he had obtained fluid, and he would not now think of injecting cocaine unless this was the case. In the one hundred and twenty-five cases in which he had used cocainization after obtaining fluid there had been two absolute failures, and in one other anesthesia was incomplete. While his results had been gratifying, it was by no means his purpose to recommend this method in all obstetrical cases. It was unquestionably a serious matter, for when the cocaine injection was once within the spinal canal it was beyond the operator's control. As to the symptoms so well described by Dr. Fowler, they were so absolutely regular that he could not regard them as due to cocaine itself. In control experiments in which he had injected saline and other solutions, the same symptoms resulted, without the anesthesia produced by the cocaine. In one case that he had seen there were chilliness, rise of temperature, vertigo, and nausea and vomiting *before* cocainization, but they all disappeared when the fluid ceased to escape. He was convinced, therefore, that it was the loss of cerebrospinal fluid which caused the symptoms, and that the latter were simply nervous phenomena, the result of shock. From his experience he believed that these symptoms could be anticipated and prevented by the use of drugs, such as the bromides. The anesthetic effect was not apparently increased by injecting a large dose of cocaine, and the mistake was generally made, he thought, of using too large a quantity. He had found that one-sixth grain was ample, and in many cases one-twelfth grain would be all that was required. Eucaine, in his experience, had proved absolutely without value. In labor, if cocaine anesthesia was complete, there was no necessity for bearing down, and the delivery would be accomplished without pain. It was of very great service in prolonged first stage. Any bad results which he had noted from its use were of an evanescent character, and gave him no uneasiness. In gynecology cocainization had but a limited field, but it was valuable in cases in which a general anesthetic was inadmissible. The method was contra-indicated in two classes of individuals. These were those on whom cocaine has no effect, and the highly neurotic.

Intraspinal Cocainization and the Anesthetist's Standpoint.—Dr. S. Ormond Goldan said that he had employed the method in thirty-one cases and that his successes had been more numerous than his failures. After eliminating as far as possible all the causes of disappointment, however, he had still continued to meet with some cases in which the method was insufficient. Of all the anesthetics ether preceded by nitrous oxide gas was the safest, while cocainization, so far as one could judge at present, was the least safe, and should be resorted to only when a general anesthetic could not be given. In his patients he never failed to get fluid before proceeding with the injection.

In the general discussion which followed, Dr. V. P. Gibney spoke with considerable enthusiasm of the value of the method in orthopedic surgery. The patients whom he had selected were usually fifteen or sixteen years old.

Dr. E. H. Grandin had not been favorably impressed by the method. In two of the three cases which he had seen, the patients being neurotic Italian women, cocainization had failed to produce anesthesia, and in the third the anes-

thesia was incomplete. In obstetrics he did not think its use justifiable. In the minor operations of gynecology, if any anesthetic at all was called for, nitrous oxide gas left little to be desired, and in the major ones a general anesthetic was preferable to cocainization.

Dr. Guiteras, in speaking of the five deaths reported by Tuffier, said that Tuffier himself seemed to think that only one of them was really attributable to the cocaine injection. He also gave a number of statistics reported by various European surgeons at the recent International Medical Congress in Paris.

Dr. W. S. Bainbridge had tested the method in a considerable number of children, whose ages ranged from two and one-half to nineteen years, and reported very favorable results. Eucaine was less efficient, as a rule, than cocaine, but in one case it produced complete analgesia when the latter had previously failed.

Dr. F. Kammerer, who had forty cases, thought the method of great service in genito-urinary surgery, but of distinctly less value for intra-abdominal work. He always used as small a dose of cocaine as possible, generally one-tenth grain, and rarely over one-fifth grain.

Dr. R. F. Weir was the last speaker. In some of the ten cases in which he had tried the method at Roosevelt Hospital he had had a great deal of anxiety for a time, and so far it had not presented itself in a very encouraging way. Out of 400 cases which he had seen recorded there were, including the five reported by Tuffier, no less than eight deaths. Still, it was too soon to form a positive opinion in regard to its efficiency, and time must be allowed for further observation.

BOOK REVIEWS.

Atlas and Epitome of Diseases Caused by Accidents. By Dr. Ed. Golebiewski, of Berlin. Authorized Translation from the German, with Editorial Notes and Additions by P. Bailey, M.D. Forty Colored Plates and One Hundred and Forty-Three Illustrations in Black. Philadelphia: W. B. Saunders & Company, 1900.

This volume considers diseases caused by accidents in their relation to the accident insurance laws of Germany. This law gives to workmen disabled by accidents, occurring in connection with their work, indemnities varying from two-thirds of their ordinary wages for total disability down, according to the degree of disability and their wage-earning capacity. This indemnity is readjusted from time to time as the wage-earning condition of the insured becomes worse or better.

The book consists chiefly of histories of cases occurring in Golebiewski's practice, illustrating the symptoms and sequelæ of accident-injuries as discussed in the text in reference to the adjustment of the accident insurance.

In this country the work will prove of value only to those physicians and lawyers (chiefly the latter) interested in settling legal claims for damages for injuries due to accidents.

The best part of the book is the illustrations, of which the colored ones are beautiful examples of the artist's and lithographer's skill. The American editor has made some additions bringing the book in accord, in part, with the laws of this country.

Transactions of the American Otological Society. Thirty-Third Annual Meeting, Washington, D. C., May 1, 1900. Vol. VII., Part III. Published by the Society. Printed by Mercury Publishing Company, New Bedford, Mass.

These transactions are remarkable for two things apart from their intrinsic value, *viz.*, their brevity and their focus. Of seven papers read, three by Drs. Hiram Woods, E. B. Dench and Ed. Friedenberg, deal with Sinus Thrombosis and Its Congeners; two by Drs. H. Knapp and G. Bacon, with Extensive Caries of Mastoid and Cerebral Abscess (and the remaining two with Chronic Ear Vertigo and Clinical Anatomy of the Eustachian Tube. Thus, five papers treated of chronic suppurative ear troubles, dangerous to life, showing how otologists recognize that they are driven into the most vigorous kind of struggle with destructive forces in the treatment of ear diseases. As one would expect, therefore, the papers throb with interest, the discussion of them not less so. Both writers and speakers are men of strength in their department and the Transactions have a corresponding value. In addition to the above, this volume contains forty-two pages of a valuable otological bibliography, alphabetically indexed for the period June 1, 1899, to June 1, 1900, compiled by Mr. Henry Alderton, of Brooklyn.

Transactions of the American Ophthalmological Society. Thirty-Sixth Annual Meeting, Washington, D. C., 1900. Hartford: Published by the Society.

Thirty-five papers were presented by twenty-eight members on fifteen phases of eye-study. There were two papers on entropion which were well discussed; six on vascular and other tumors of the eye and orbit; five on intranasal conditions; five introducing new apparatus; five concerning the sight-perceiving elements; three about lens conditions and one each on surgical treatment of high myopia, excision of the lacrimal sac, disease of the choroid, treatment of dendritic keratitis, glaucoma, histology of the lacrimal gland, spastic strabismus and pseudo-sympathetic inflammation from blind eyes.

Two of the new devices are lanterns for testing color-perception presented by Drs. Wm. Thomson and C. H. Williams. The intranasal conditions are affections of the accessory sinuses involving the orbit and pressure symptoms between the middle turbinate and the ethmoid cells—headaches like those from ocular asthenopia. In these latter the treatment is radical, *i. e.*, removal of the turbinate. The charts are placed where they belong in the text and thus add greatly to the value of these transactions.

Manual of the Diseases of the Eye. By CHARLES H. MAY, M.D., Instructor, Eye Department, in the College of Physicians and Surgeons, Medical Department of Columbia University. New York: William Wood & Company, 1900.

THIS new manual for students and general practitioners treats diseases of the eye in "a concise, practical and systematic way," as the author states it. The book is small enough to go into the pocket, yet it is comprehensive of its subject. It is "up to date." The arrangement is excellent, because it takes up the subject just as the specialist would take up and carry through a thorough examination of the patient. Besides it completes the treatment as it goes along. When an operation is needed, it is done. Thus, the book interests one from the start. Scientific use of laws of optics comes in for its proper share of attention well on in the book after interest has been aroused and maintained and need for the knowledge in its application to lenses has arrived. Two figures, 168 and 175, are especially helpful to lucidity. When the avowed purpose is considered and originality is disclaimed, the work has merit in all its features.

Original Contributions Concerning the Glandular Structures Appertaining to the Human Eye and its Appendages. With Seventy-One Original Illustrations. By ADOLPH ALT, M.D., Professor of Ophthalmology in Beaumont Hospital Medical College, St. Louis. American Journal of Ophthalmology, St. Louis.

AFTER years of patient dissection and work with the microscope, Dr. Alt has given us the result of his investigations on the histology of the glands pertaining of the eye, in a book with only a few pages of text but beautifully illustrated with seventy-one original illustrations. This field has not been much worked. The author's studies substantiate the findings of A. Tersen of Paris, and their two works stand alone as complete monographs on the subject. They show, among other things, that there are many glands in the eyelids of like structure with the lacrimal gland and which evidently perform the same function, enabling the eyes to endure without detriment, abation of the larger gland. The plates with their explanatory notes give us a valuable and needed addition to the literature on the eye.

Pathology and Morbid Anatomy. By T. HENRY GREEN, M.D., F.R.C.P. Ninth American Edition, Revised from the same English Edition. Lea Brothers & Co., Philadelphia and New York.

DR. GREEN'S book of pathology has been so extensively welcomed in the past that it needs no words of introduction at this time. To those who had the opportunity of knowing the previous editions, it will at once be evident that the old arrangement has largely been adhered to; some of the sections, notably those treating of hematology and neuropathology, have undergone considerable revision and addition. The admirable plates of the malarial parasites will be welcomed by all students; the cycle of development is so well shown that any text almost seems superfluous. The etiological consideration of the malarial fevers has been brought up to date by a short mention of the mosquito in this connection, as well as by the drawings of the Culex and Anopheles. In the matter of drawings it is to be regretted that so few are of the same excellence as those found in the chapter on blood.

Some excellent text-books on pathology have made their appearance on the American market within the last two or three years; just what porsition will finally be accorded each will be interesting, but it would prove unwise to predict at the present time. Dr. Green's book has done good service in the past and no doubt many will still consider it an excellent book for students.

BOOKS RECEIVED.

A CLINICAL TREATISE ON FRACTURES. By Dr. W. B. Hopkins. 8vo, 268 pages. Illustrated. J. B. Lippincott Company, Philadelphia.

EXPERIMENTAL RESEARCH INTO THE SURGERY OF THE RESPIRATORY SYSTEM. By Dr. G. W. Crile. Second Edition. J. B. Lippincott Company, Philadelphia.

THE ESSENTIALS OF PRACTICAL BACTERIOLOGY: An Elementary Laboratory Book for Students and Practitioners. By Dr. H. J. Curtis. 8vo, 200 pages. Illustrated. Longmans, Green, & Co., New York, London and Bombay.

TEXT-BOOK OF PHYSIOLOGY. Edited by E. A. Schäfer, LL.D., F.R.S. Volume Second. 8vo, 1363 pages. Illustrated. The Macmillan Company, New York.

MUSHROOMS, EDIBLE AND POISONOUS. Studies of American Fungi. By Geo. F. Atkinson. 8vo, 300 pages. Illustrated. Andrus & Church, Ithaca, N. Y. $3.00.

MASSAGE IN RECENT FRACTURES. A Series of Lectures. By W. H. Bennett, F.R.C.S. 8vo, 97 pages. Illustrated. Longmans, Green, & Co., New York, London and Bombay.

THE PRESENT POSITION OF THE TREATMENT OF SIMPLE FRACTURES. An address. By W. H. Bennett, F.R.C.S. 8vo, 40 pages. Longmans, Green, & Co., New York, London and Bombay.

THERAPEUTICS: ITS PRINCIPLES AND PRACTICE. By Dr. Horatio C. Wood. Eleventh Edition. By Drs. Horatio C. Wood and Horatio C. Wood, Jr. 8vo, 850 pages. J. B. Lippincott Company, Philadelphia and London.

ORIGINAL ARTICLES.

LAKEWOOD AS A WINTER RESORT.

BY WILLIAM GRAY SCHAUFFLER, M.D.,

OF LAKEWOOD, N. J.

WHILE much is written in the daily papers about Lakewood as a fashionable resort during the winter months, and many people know of it as a place in which to spend a jolly holiday season, few stop to think why it is so attractive to the tired city folk, and fewer still appreciate the reasons that make it more than an ordinary pleasure ground.

It will be my aim in the first place to bring together facts showing the physical characteristics of the place, and in the second place to give my reasons for regarding Lakewood as unique among the resorts of this country.

The village of Lakewood was known until 1832 as Washington Furnace, then until 1865 as Bergen Iron Works, and from then until 1880 as Bricksburg. Since 1880 its name has expressed the two main natural features of the place, a lake surrounded by woods. In earlier years, as the name implied, Lakewood was given over to the iron industry, and also derived some importance from its situation on the highway from Freehold, the county seat of old Monmouth County, to Toms River, the most important seacoast town of the vicinity.

Lakewood is distant from Jersey City, Philadelphia and Atlantic City about sixty miles by rail, and is very easy of access from all of these cities, express trains covering the distance in from one and a half to two hours. It is also easily reached by carriage from the sea-coast, being but nine miles from Point Pleasant and ten miles from Toms River. As the crow flies, the sea-coast is but seven miles off, in a southeasterly direction, and in the spring and summer, sea-breezes tempered by sweeping through the pines, give Lakewood a whiff of salt air.

The peculiarities of situation and surroundings which make Lakewood unique in the Northern States are due to its sandy soil and pine forests. There is a pine and sand belt from 8-20 miles in breadth, stretching inland from the coast for about sixty miles, and on the northern border of this belt lies Lakewood.[1]

The depth of the sand varies throughout this extent. At Lakewood it has been shown to reach a depth of from 500-600 feet, thus furnishing the driest possible soil. The pine forests extend in all directions and are especially thick to the north and west. As the prevailing winds during the fall and winter come from these directions, they are necessarily much tempered by blowing across these great areas of pine woods, losing thereby some of their harshness. It is a popular notion among many frequenters of Lakewood, that they derive great benefit from breathing in the pine air. This theory, while it may not rest on a scientific basis, does much good in encouraging people to live out-of-doors, and can therefore be conscientiously encouraged.

A great deal has been written and said about the temperature of Lakewood being from ten to twelve degrees warmer than that of New York, and this statement even finds a place in Solly's Medical Climatology. While this is partially true, it is somewhat misleading and should be carefully explained. There is no doubt that warm weather holds until later in the fall, and commences earlier in the spring than in the surrounding cities, but during a cold snap the thermometer goes down to fifteen or ten or even five degrees above zero. It rarely stays low for any length of time, and the great preponderance of sunny days gives the sensation of greater warmth than the thermometer actually shows.

The greatest factor in the apparent warmth of the climate is a low percentage of humidity. Records which I have kept by means of a Draper self-recording thermometer give the average temperature for the winter season of 1899-1900 as follows: October, 63.39° F.; November, 52.53° F.; December, 44.85° F.; January, 42.89° F.; February, 40.94° F.; March, 46.71° F.; April, 57.97° F.; May, 63.16° F.

During this time there were several cold snaps which brought the averages somewhat lower than in other years. But cold weather, that is with the thermometer below 32° F., almost invariably means bright sunshine, and a cold damp day is the exception.

The average height of the barometer from October, 1899, to June, 1900, was 30.07 degrees. The record of humidity in Lakewood is something quite surprising. There being no self-registering hygrometers it is impossible to keep an accurate record, as the variations are so sudden that there will often be a difference of 40 per cent. in half an hour. The figures I shall give have been observed by me personally, and as far as they go, are accurate.

I would call the average humidity of Lakewood for the hours from 9 a. m. to 5 p. m. about 45 per cent. Before and after these hours it runs up from 65 per cent. to 85 per cent. A very common reading from 11 a. m. to 3 p. m. is 25 to 30 per cent. On November 21st I made the following remarkable observation: After a sudden and very heavy rain-storm lasting about one hour, the thermometer dropped 20 degrees,

[1] See The Pine Belt of New Jersey. Isaac Hull Platt, M.D., Transactions of the American Climatological Association, 1889.

the barometer rose 0.35 degrees, and the hygrometer registered 0 per cent. Not believing such a thing possible, I carried the instrument into the house, when it promptly rose to 60 per cent. On placing it again out of doors in the wind, which was blowing strongly from the south, it dropped again to 0 per cent. and stayed there for about two hours. I have frequently seen the instrument at 15 per cent. to 20 per cent. for hours at a time. All this goes to show, not that Lakewood is the driest place in the United States, for that is not so, but that the average humidity is low, and at times, and that almost daily, there is no appreciable moisture in the air.

As I have said before, this state of things is brought about by conditions of soil and surroundings which are unique in a northern climate. Let me give one recent instance of the rapidity with which moisture disappears. On December 21st last, between 4 and 5 p. m., five inches of snow fell. The morning of the 22d was crisp and cold, with brilliant sunshine. In the afternoon it grew warm, and during the night the snow melted rapidly. On the 23d it rained, and by the morning of the 24th every vestige of snow had disappeared, the ground was bare and the principal streets were dry enough for bicycling. This condition of heavy rain and snow, followed within forty-eight hours by dry roads fit for walking or wheeling is a very common one. The percentage of sunshiny days is very large, and this fact adds greatly to Lakewood's usefulness as a resort.

The depth of the sandy soil guarantees a perfect water-supply. The large hotels and some individuals have sunken artesian wells from 500 to 700 feet in depth, and have thus secured for themselves an inexhaustible supply of the purest water. The village at large is supplied from a series of artesian wells combined with lake-water which filters itself through several feet of sand into earthen pipes. This water has been shown by careful analysis to be entirely fit for drinking and cooking purposes. A carefully planned and regulated system of drainage is under the same supervision as the water-supply, and no pains are spared by the authorities to keep the drainage and water-supply as perfect as possible.

Lakewood's population consists of the regular inhabitants and the guests at hotels and cottages. The former amount to between two and three thousand, and this number is nearly doubled during the height of the season. A more cosmopolitan population one would have much difficulty in finding. All the large cities of the east send their regular contingents, and it is a common saying among old residents that if you will have patience you will in time meet every one you ever knew at one or the other of the hotels. The residents have done a great deal to beautify the village, and they take both pride and pleasure in doing so.

With all these natural advantages it is not difficult to see why Lakewood should be especially adapted for a winter resort. But the natural advantages alone would not induce so many hundreds of people each season to spend weeks and even months in this little village. To Nature's best, there have been added in the way of hotel and cottage accommodations all that man's ingenuity can invent. The large hotels provide the very best accommodations possible, with cuisine and service not surpassed anywhere, and in the small hotels and many excellent boarding-houses are accommodated hundreds who prefer a quieter and simpler life than the hotels afford. Nowhere in this country or abroad are the wants of the guests more carefully attended to and their welfare more fully consulted. And yet Lakewood does not give a stranger the impression of being full of invalids. Sick people there are in abundance, but they do not obtrude themselves upon the sight and attention of the well.

The great proportion of pleasant days make all outdoor sports possible to a far greater extent than is usual in our Northern States. Golf goes on throughout the fall and winter with such regularity, that tournaments, calling together the leading amateurs of the country, have become fixtures for Thanksgiving, Christmas and New Year's, and Lincoln's and Washington's birthdays. The hard, level roads are most inviting to wheelmen, and horseback-riding claims a large number of devotees. Hunting and polo-playing offer attractions to the more venturesome riders and the beautiful walks and drives into the woods in all directions give ample opportunity for all to enjoy exercise and fresh air.

The Lakewood season has for twenty years commenced with the opening of the Laurel House on October 1st and closed on June 1st. During the summer months few remain, but those who do so report almost uniformly pleasant weather, with periods of intense heat and frequent heavy thunder-storms.

In my opinion Lakewood owes its usefulness as a health resort chiefly to two factors, its comparative mildness of temperature and its phenomenal dryness. These two facts make it possible for chronic invalids and those recovering from acute illnesses to spend a large portion of their time out-of-doors in the bright sunshine. When to this are added the inducements to active exercise offered by bicycling and golfing, and the fact that these pastimes are possible nearly all winter long, owing to the extreme dryness of the soil, it is readily seen why people in all stages of weakness and strength are attracted.

While the newspapers have given Lakewood a certain degree of notoriety as the winter home of not a few society people, the majority of those who build houses and spend the winters here, originally settled on Lakewood as their home because of benefits which some members of their families have derived from the climate. This class of cottagers is slowly and steadily increasing.

This leads me to speak of a few of the conditions for which I believe Lakewood to be especially beneficial. Patients suffering from asthma find speedy and often permanent relief. Various forms of bronchial and laryngeal disease yield more quickly to treatment when combined with the out-of-door life possible here. Patients in the very first stages of tuberculous trouble often are able to arrest the process by a residence at Lakewood. But I wish just here to enter a strong protest against the custom of some physicians of sending advanced cases of phthisis to Lakewood, assuring the patients that a few weeks will make new men of them. My own firm conviction is that such cases do badly here, and should not be encouraged to come.

Other patients who do well at Lakewood are those convalescing from acute diseases. The change of scene from city life and surroundings and the constant incitement to outdoor exercise help to bring back appetite and strength. But here too, I wish to utter a word of caution. Too many patients come to Lakewood with instructions from their home physicians to "live out-of-doors." Consequently they start out by overdoing physically, and soon find themselves languid and overwrought, and instead of the rapid gain promised, they feel worse than when they left home. This condition could easily be avoided if the home physician would only insist on moderate exercise at first, increasing with the added strength gained. This may seem a small point, but by its careful observance, much harm can easily be prevented.

One more class of people derive marked benefit. To sufferers from the various forms of neurasthenia Lakewood offers especial attractions. From a rather extensive experience with such cases, I have reached the conclusion that nearly all forms of nervous prostration and excitement can be helped greatly. There is something in the atmosphere and surroundings which seems to have a quieting effect on overwrought nerves. It is a very common observation, even among laymen, that for several days after coming to Lakewood, one is constantly sleepy, showing how the nervous tension relaxes.

In what I have said I do not pretend to exhaust the list of conditions which make Lakewood what it is. I have simply touched on a few practical points. There is one more practical point which may be spoken of, and that is the expense of sending patients to such a place as Lakewood. It is often said that Lakewood is too expensive a place for many people to come to. Regarded simply from the economic standpoint of staying at home, the criticism is well taken. But when we take into consideration that other suitable and cheaper places, such as the far south or the far west can only be reached by long and expensive railway journeys, the matter of expense will not seem so great. Good accommodations can be secured from $2.50 a day up. Some few houses furnish lower rates, but the average is about $25.00 per week per person.

In closing let me remind you that Lakewood does not pretend to the dignity of a European Spa. It is simply a nearby country village, pretty and attractive, dry and sunshiny, free from malaria and infections of all kinds, so situated that outdoor life is possible nearly every day during the winter, and where delicate men, women and children have for many years past found returning health and vigor.

THE CLIMATIC TREATMENT OF CHRONIC BRIGHT'S DISEASE.

By JAMES TYSON, M.D.,
OF PHILADELPHIA;
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.
AND
T. MELLOR TYSON, M.D.,
OF PHILADELPHIA;
ASSISTANT PHYSICIAN TO THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA; VISITING PHYSICIAN TO THE RUSH HOSPITAL FOR THE TREATMENT OF CONSUMPTION.

It is to be regretted that our knowledge of the effects of climate upon Bright's disease must be expressed for the most part in generalities, because almost no systematic observations have been made as to such influences. What has been done in this direction has been chiefly collection of mortality reports in certain districts which have been compared with each other.

Reasoning from general principles, we conclude that by far the most important factor in the treatment of chronic Bright's disease is that there should be as little cold, moisture and variation in temperature as possible. Hence, the hot, dry climate should be more beneficial than a cold, dry climate; either is better than a temperate climate, such as that found in the United States, with ground saturated with moisture and consequent dampness, with sudden changes of temperature, and marked difference between the day and night temperatures. It is acknowledged that renal disease is more prevalent in such a temperate climate, less in a cold, and rare in a warm. The kidneys do more work in a changing temperature climate and, therefore, are more subject to derangement, while in a hot climate the liver and skin are more disposed to disease, and in a cold climate the lungs. These tendencies must, of course, be influenced by such conditions as overwork, worry, syphilis, gout and excessive use of alcohol. In view of the increased function of the skin and kidneys through the ingestion of water, generally taken in large quantities, the hot, dry climate would seem best adapted to influence favorably renal disease.

Another important agency is the effect of winds, which are known to be very detrimental and which are met with in all, although they are more prevalent in cold climates.

Dr. S. E. Solly, in his book on Medical Climatology says, "The direct tendency of altitude in chronic nephritis, as in most chronic diseases, is toward its cure. This beneficial influence is, doubtless, mainly exerted through the increased

action of the lungs, and to a smaller extent, of the skin, which lessens the work of the kidneys, and diminishes the renal congestion by the general stimulating and equalizing of the circulation." He also states that he prefers a warm, low, inland climate, such as Egypt and Arizona, for the majority of cases of chronic Bright's disease. This is confirmed in part at least by Purdy's studies, which show a low rate of mortality in the South Mississippi river belt, where the mean elevation is 100 to 300 feet, the rainfall 50 to 55 inches, the mean temperature 60° to 65° F., and the death-rate from Bright's disease 3.14 per 1000 deaths, as determined from the census of 1880. The Southwest central region, with an elevation of 100 to 500 feet, rainfall of 35 to 50 inches, temperature of 60° to 70° F., has a mortality of only 1.97 per 1000. We cannot but think that some of these results may be due to the difficulty of securing accurate statistics in these regions. Based upon a record of the mortality of the disease, the States most unfavorable for patients suffering from renal disease are New Jersey, New York, Massachusetts, New Hampshire and Vermont, and those most favorable Tennessee, Georgia, Nebraska, North Carolina, Arkansas, Texas and certain parts of Southern California. It will be seen that the States that are the most favorable have about the same climatic conditions—even temperature, dryness and warmth, with less amount of wind velocity. This is the reverse in the States in which the mortality is greatest, and the climatic condition is one of moisture, changeability of temperature with coldness.

In grouping together large areas we find that the mortality is highest in the Middle Atlantic Coast region, next in the North Atlantic, and next in the Northeastern hills and plateaus, the South Atlantic Coast region, and, lastly and least, in the Southern Central region. In trying to explain the great variations in the death-rate in these different locations, Purdy rightly says that it is not to the climatic conditions alone in the Middle Atlantic Coast region that we must ascribe the greater number of deaths, but we must consider also the larger population, the habits and social condition of those living in the large cities, as well as the greater prevalence of certain diseases, like syphilis, scarlet fever and pneumonia, which predispose to Bright's disease. In the North Atlantic Coast region, in which we do not find the same social condition and as many of the diseases causing Bright's disease, but where the climate is far worse than in the Middle Atlantic region, we must admit a larger influence of climate.

In the Northeastern hills and plateaus, where the mortality is still less, there is more evenness of temperature than in the other two regions, although it is very cold and the winds are high; we must conclude that the lessened mortality is due to the small amount of moisture. Again, in the Southern Atlantic regions there is a low death-rate, and since moisture is more conspicuous, we must conclude that equality of temperature and diminished wind force are responsible factors.

Another feature which must be remembered in sending a patient to the region most suitable to his condition is that most cases of chronic Bright's disease have either a failing heart or one that has already lost compensation. Hence, we must not only decide upon a climate and an altitude suited to the renal affection, but also one that is adapted to the cardiac condition—a fact which makes the problem still more difficult. For such cases high altitudes are harmful.

TREATMENT OF SYPHILIS AT HOT SPRINGS, ARK.

By JAMES T. JELKS, M.D.,

OF HOT SPRINGS, ARKANSAS;

PROFESSOR OF GYNECOLOGY AND SYPHILOLOGY IN BARNES MEDICAL COLLEGE, ST. LOUIS, MO.; FORMERLY PROFESSOR OF GENITO-URINARY SURGERY AND VENEREAL DISEASES IN COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO; PHYSICIAN AND SURGEON TO THE OZARK SANATORIUM.

Syria and Chaldea—the latter having for its capital Babylon—were noted in ancient times as centers of debauchery. On the Assyrio-Babylonian cuneiform inscription tablets in the British Museum, derived from the royal library of Sardanapalus, it is related that Istar, the goddess of sinful love, proposed to Nimrod to become his wife, a proposition which the latter very ungallantly refused. Istar demanded satisfaction for this insult from her father, Anu. As a result, the sacred bull was sent against Nimrod and his friend Eabani. Eabani seized the animal by one horn and the root of its tail, while Nimrod fatally bored its heart with a weapon. Istar uttered an awful curse, to which Eabani replied by tearing out the penis of the bull and throwing it full in her face. A new curse was hurled by the goddess, and Eabani died after a short illness. Nimrod was likewise attacked with a painful disease. He wandered about until he reached the infernal regions, where he was given "magic food" for his complaint. This remedy apparently had no effect, for Nimrod continued to complain that the shadow of death lay on his genitals. The god of the infernal regions then took him to the ferryman, and bade him take the hero to the fountain of life, saying: "The man whom thou hast taken has his body covered with pustules; scales have altered the fairness of his body. Take him to the cleansing place, where he can wash his pustules clean and take off his skins; the water will carry them off; his body will appear well. The coverings of his head will be renewed, also the coverings of his shameful parts; by the time he returns to his country there will be no folds; all will be new." Then follows, after an interruption in the text, "He renewed his head coverings; the sheath which clothed his shameful parts was new when he reached his native land." Eabani evidently had lues, for Nimrod prayed that he might not die like his companion.

From mythological times the people have sought a fountain which to them should be a fountain of youth. So with us, from the time whereof the memory of man runneth not to the

contrary, this place has been the Mecca of syphilitics. In the mind of the laity the springs have been regarded as a specific for this disease. That these unfortunates do find relief from their sufferings in an almost incredibly short space of time cannot be denied.

Why do they get well here so much more rapidly than elsewhere? In the first place the hygienic treatment of this disease does not receive the attention which it should at the hands of the general practitioner or the specialist in our towns and cities. And yet this is the first line of treatment laid down by all syphilographers, and after it, and along with it, comes the specific. And whether we will or not, this class of patient get both lines of treatment in perfection. The patient, it may be, comes from the crowded and rushing life of the city and finds here all the comforts of the city plus something more—the exhilarating life of the pure country air, laden with all the ozone and freshness of the Ozark Mountains—from the dust and hurry and strife of the busy city to the quietness and freshness and greenness of the forests, to a home in the woods, practically, for the forests are all about him. Here he may spend, not only a few hours, but all of his days, under the shade of the trees. From business cares to absolute rest; from worry to peace; from the noise and dust and turmoil, if he wishes it, to a perpetual Sabbath. He may sit in the beautiful park on Hot Springs Mountain and see the world pass beneath him and he simply a looker-on. From feeling himself an outcast, with the mark of Cain on his brow, he here finds congenial spirits who take him out of himself and make him forget that he is afflicted with a loathsome disease. He sees so many getting well around him that hope springs up in his breast and he once more takes up the battle of life with renewed energy. As a result of all these influences his vital processes are quickened, his worry disappears, his appetite and digestion become perfect, his assimilation is improved, and everything with him goes well. From despair there is a rapid change to renewed hope and determination.

Physicians everywhere know how difficult it is to get a walking patient to do anything thoroughly; know how difficult it is to get a man who does not feel very ill to take medicines promptly and regularly; while the same man here will obey his physician absolutely. At home he does not appreciate this necessity, but here, in Hot Springs, he makes a business of getting well and does it. If we tell him to stop using tobacco he will do it. If he has been accustomed to alcoholic drinks he will not touch them. If he has been dissipating by keeping late hours, he will retire at any time we tell him. If the pleasures of the table are a temptation to him, on the order of his physician he will lead an abstemious life. In other words, we have him under perfect control and we may do with him whatever we wish.

Aside from all these hygienic advantages of which we avail ourselves to the utmost, we have unequaled bathing facilities in these far-famed waters. How do they act in this class of patients? We have the patient infected with a specific microorganism, the bacillus of Lustgarten, the organism recently described by Neusser, diseased white blood-corpuscle of Otis, or whatever one may please to call it. One thing that we do know is that in this patient's blood and tissues there is circulating a pathogenic microbe, with all its consequences. And what are they? Primarily, a disease of the lymphatic system, the whole blood soon becomes impregnated, nutrition is interfered with, the victim becomes hydremic, and the blood, loaded not only with the micro-organisms of disease, but with an excessive amount of the "blood-dust" of Müller; and along with this blood-dust there are toxins which accompany the life-history of all growing bacilli.

Toxins, blood-dust and pathogenic organisms, and, following in their wake, or as a result of their presence, mental depression, worry, indigestion, and malnutrition, each reacting on the other, and there is developed a vicious cycle which will not and cannot be broken at home. All these things break down and cripple those marvelous little friends of ours—the phagocytes, or white blood-corpuscles. They are overwhelmed in their task of eating up or destroying the germs and their toxins, and the result is faulty metabolism and all the ills that flow from this state of things.

While in this condition the patient comes to the Hot Springs and commences the business of getting well. The hygienic treatment above alluded to is supplemented by the baths and drinking of the hot water. The excessive amount of blood-dust is rapidly eliminated, toxins are washed out, and the phagocytes have an opportunity to assert themselves, and a fighting chance with the micro-organisms of the disease. While this is going on the patient receives specific treatment. By this the red corpuscles are increased in numbers and the hemoglobin rapidly rises to normal. Almost before the patient knows it he finds himself gaining in flesh and healthfulness.

We take it that these waters act as a powerful eliminant for dead and effete material, and thus stimulate tissue metabolism wonderfully. The stomach, skin and kidneys are profoundly impressed by its free use, and thus digestion is aided, tissue change promoted, dead material washed out, the toxins, of whatever nature they may be, eliminated, and Nature given a fighting chance with disease germs and their products. After all, there are not many specifics in medicine. Nature has provided the phagocyte, or white blood-corpuscle, for our protection. If this defender of the body is in good fighting trim the invading enemy will be overcome and the toxins they produce in their life-history will be eliminated by the skin and kidneys.

Aside from the specific contagious diseases which afflict humanity, practically all the ills of mature life, and many of those of younger people, are produced by faulty metabolism, defective elimination of tissue waste and toxins, which have

been made by bacteria of various kinds which gain entrance into the economy through the intestinal and respiratory tracts. "The battle of the cells" of Virchow is a reality, we all know to-day, and our bodies are the battle-ground. The invading germs are met at the threshold by the defenders, our good fairies all arrayed in white; not as the fairies of good Queen Mab, clothed in green, but in white—the white corpuscles of the blood, armed not only with this power to attack and digest the invader, but also with the ability to furnish an antitoxin which will neutralize the toxins of bacterial origin. These antitoxins are called alexins, and, together with the germ-destroying power of the white blood-corpuscle, are Nature's provisions for protection against an enemy which has gained an entrance into the blood. This power cannot be properly exercised if the skin, stomach, liver and kidneys are not doing their work in a perfect manner. Failure of eliminating organs to get rid of the results of tissue metabolism clogs the machinery of life, cripples and poisons these little and powerful defenders, and the result is disease in some one of its many forms.

It has been demonstrated by Reiss and others that the red cells are decreased in numbers shortly after the initial lesion is observed, and that this decrease continues until the secondary symptoms appear. The hemoglobin also sinks from the very beginning of the disease.

Konried ascertained that during the first four to seven weeks the red cells remain normal in number, but that the hemoglobin decreased and continued to decline until treatment was begun. In two hundred examinations, Newman and Konried reported that up to the appearance of the secondary symptoms twenty-five to thirty per cent. of hemoglobin was lost, with a considerable decrease in number of the red cells.

Lezius found that the diminution in the number of red cells occurs at the outbreak of the eruptions, and that the hemoglobin may sink as low as twenty-five per cent.

A very remarkable thing occurs with the white cells. Leucocytosis always takes place. Microscopical examination of the blood will show a very large increase of these defenders. There are a great number of lymphocytes present in this class of cases, and many eosinophiles may be found. In this increased leucocytosis Nature's effort to destroy the invading micro-organism is evident. Under appropriate treatment, with the baths an adjuvant to get rid of the *débris*, the toxins are washed out.

Administration of the iodides and mercury is followed by decrease in the white and an increase of the red cells. These remedial agents go to the assistance of the white cells. The germs of disease are destroyed and the leucocytes find themselves out of employment and decrease until they reach the normal.

It has been demonstrated that the exhibition of mercury increases the count of red cells for the first three or four weeks of its use, and that after a time, if it is continued, there is also a loss of both the red corpuscles and the hemoglobin. The same thing is true of the use of the iodides. Hence we find that when these remedies are pushed for too long a time or in too great quantity, the patients lose ground; especially is this true when the elimination of the remedies is not encouraged by the use of baths.

By reason of the very rapid elimination of medicines produced by the drinking of and bathing in these waters, we may give much larger doses of the remedies required in the treatment of disease than is usually tolerated by the patients in their homes. Instead of twenty grains of iodide salts, three times daily, it is a common thing to give fifty to one hundred grains at a dose. When the gummatous infiltration threatens the eye, the hard and soft palate, the brain or spinal cord, we do not hesitate to give one thousand grains a day. Of course, these large doses are exceptional, and are given only when some very urgent demand exists. We have learned that each patient must be a law unto himself—what one man bears with impunity another cannot take; that each man has his dose, beyond which he cannot go. Commencing, then, with fifteen to twenty-grain doses, we push the remedy until the patient suffers from iodism, or until the symptoms for which it is given yield to the remedies, even if it takes one thousand grains a day.

In the same manner we use mercury in such doses as the patient may need, whether that may be one dram of mercurial ointment daily, or four times as much, always bearing in mind the physiological and pathological effect of the remedy on the blood-corpuscles.

We prefer mercurial ointment to any other form of administration. It does not disturb the stomach and bowels, save in exceptional cases; and in these cases the remedy by the mouth would scarcely be tolerated at all.

Under the microscope the blood-dust will be found to have diminished greatly, the red blood-corpuscles increased in numbers, the hemoglobin become normal and the patient well.

This we have seen so often that we can promise a patient absolutely that his syphilide will disappear promptly under the influence of the baths and specific medication in a very short time. How short? Well, for all the secondary eruptions, from ten days to six weeks. His skin will become as it was with Nimrod, white and soft and clear; his spirits will revive; his digestion will be all right, and he will gain from ten to thirty pounds in weight. Can the physician in the ordinary lines and places of practice make good any such promises as these?

218 Central Avenue.

Exposed Others to Small-Pox.—Dr. M. J. Rodermund of Appleton has a theory that smallpox is not contagious. He tried to show the correctness of his theory last week and is said to have deliberately exposed half the town after smearing himself with poisonous pus taken from the face of a patient.

SOME TOPOGRAPHICAL AND CLIMATIC FEATURES OF THE FLORIDA PENINSULA; WITH SPECIAL REFERENCE TO ITS ADAPTIVENESS AS A WINTER HEALTH RESORT.

BY JAMES K. CROOK, A.M., M.D.,
OF NEW YORK.

THE State of Florida extends from 24° 30′ to 31° N. latitude and from 80° to 87°, 45′ W. longitude. It has a coast line of 472 miles on the Atlantic Ocean and 674 miles on the Gulf of Mexico, and an average breadth of about 90 miles. Topographically the State is often described in encyclopedias and geographical works as being flat and uninteresting, or as made up of a succession of miasmatic swamps, lakes, and savannas. While by no means of a rugged character, the surface is far from being a dead level. It may more properly be described as forming the top of a submarine mountain chain, rising gradually, as it does, from both coasts to an altitude near the center of from 100 to 300 feet. The ledge forming the backbone of the peninsula is composed of the Eocene limestone, known as the Vicksburg. This formation persists from the northern limit of the State to Cape Sable, and forms the bed of all the lakes and rivers except the salt water bodies composing the east coast lagoon, extending from Pablo Beach to Cape Sable. This limestone base persists to the Gulf coast on the west side and outcrops into Tampa Bay. The great coquina ledge of Florida, probably of post-Pliocene origin; extends along the east coast from Pablo Beach to Cape Florida. The interior elevated ridge or backbone traverses the peninsula down to about the 27th parallel of latitude, the apex of the divide being perhaps one-third nearer the Gulf coast than the Atlantic. The surface of the water-shed and its western slope is generally undulating and occasionally hilly, in some sections being much broken by lakes and small elevations known as sand-hills. Along the east coast and in the St. John's River region the character of the surface is usually level. The soil, as a rule, is sandy and very porous in the hilly sections, but firmer and more compact along the level reaches. A striking feature of the surface is the immense tract lying south of Lake Okeechobee, known as the Everglades. This great morass or swamp is 160 miles in length and 60 miles in breadth, its depth varying from one to six feet. During the wet season from June to October it is impassable. The presence of this big marsh, which is always made prominent in works descriptive of Florida, has no doubt acted to the prejudice of the State as a resort for invalids. It should be borne in mind that the Everglades, though very extensive and decidedly unattractive as a near neighbor, are located far down the peninsula, below the 27th parallel and remote from the customary haunts of the tourist and the health-seeker. At some future day the enterprise and ingenuity of man will be turned upon this desolate wilderness and it will be made to blossom as the rose.

The rivers of Florida are numerous and some of them afford excellent facilities for internal navigation. The most important of these is the St. John's which rises in the great southern morass just mentioned and reaches the ocean after a northerly course of more than 300 miles. The river traverses many romantic and picturesque lakes in its route, and with its tributaries affords a navigable stretch of more than 1000 miles. The Florida rivers are supplied both by the numerous lakes and savannas, where rain-water collects, and by subterranean springs, many of which afford immense volumes of water of crystal purity and clearness. The greater part of the State is still covered with vast forests of pine, magnolia, laurel, live- and water-oak, and other valuable timber.

Florida possesses a climate which is properly described as one of the most genial and equable on the continent. Occupying, as it does, a situation between the temperate and tropical regions, it enjoys exemption in a great measure from the frosts and sudden changes of the one, and the continuous, debilitating heat of the other. Owing to the conformation of the State, being an elongated and somewhat narrow peninsula, the climate is materially influenced by the sea-breezes which sweep over the surface from the two vast bodies of salt-water which it divides. It may be characterized as a marine, in contradistinction to a continental climate. Two important climatic features are prominent, viz., pronounced equability and almost uniform mildness. It is questionable whether the proximity of the Gulf Stream to the peninsula modifies the temperature as much as has been supposed. The United States coast surveys have established the fact that the deep Arctic currents in flowing south shoal up on the east coast of the peninsula inside of the Gulf Stream. As a natural result the superjacent atmosphere is deprived of any small modicum of increased temperature gained from the latter current in these latitudes by the time it reaches the coast.

The mean annual temperature varies from 69° F. at Sanford to 68° F. at St. Augustine. For the winter months the temperature ranges from 54.6° F. at Pensacola to 66.5° F. at Jupiter. The average yearly rainfall varies from 53.19 at Pensacola to 57.16 at Cedar Keys, while the mean annual relative humidity ranges from 76 per cent. at Pensacola to 80 per cent. at Cedar Keys. According to General Greeley's estimate, based on ten years of observation, from 1876 to 1886, the absolute humidity for the northern part of the State for the month of January was 3 grains of water per cubic foot of air; for the base of the neck of the peninsula, 4 grains per cubic foot; along the 28th parallel of latitude, 5 grains per cubic foot, and at Key West, 6 grains per cubic foot. The amount of absolute humidity for the entire State for the month of July was 9 grains per cubic foot. It will thus be seen that, while the climate of Florida can by no means be properly characterized as dry, it is not, on the other hand, excessively humid. The annual mean relative humidity of the State of New York is 75 per cent. What may be termed the "dry season" in Florida occurs during the winter, the summer and early

autumn months affording by far the greater amount of precipitation. As a rule the first approach of the dry season is made in October and from the minimum precipitation which takes place in November; there is a partial resumption of rains apparent in midwinter, to be followed by two or three months of diminished rainfall.

According to data furnished to the writer by Dr. Murray W. Seagears of St. Augustine the average monthly precipitation at that point in inches and tenths of inches is as follows: January, 3.0; February, 3.0; March, 2.9; April, 2.0; May, 4.4; June, 4.9; July, 6.0; August, 5.0; September, 7.4; October, 4.1; November, 3.2; and December, 2.5.

The weather, however, cannot be relied upon implicitly. Blodgett pointed out many years ago the great irregularity of the winter rainfall on the peninsula for different years. One season is no reliable guide for another, and we must take the average for a number of years to reach an approximately correct figure. The equability of the Florida winters is occasionally interrupted for a day or two, possibly for several days, by a north or northwest wind of a cold, dry character, known as the anti-cyclone and resulting from abnormal distribution of atmospheric pressure. Its approach is signaled by a drop of from 10° to 30° F. in twenty-four hours. This wind finds its analogues in the *mistral* of the French Riviera, the northeast *gregale* of Malta, the northerly *transmontana* of the Adriatic, and the *bora* of Trieste and Dalmatia. South of the 29th parallel these atmospheric disturbances lose much of their force and are hardly to be regarded as a serious drawback.

Heavy dews are also a prominent feature on clear, still nights, and fogs are not infrequent, especially along the Atlantic coast and St. John's River district. These have been attributed to the level character of the section, to the presence of large bodies of comparatively still fresh water, and to the winds from the Gulf Stream, warmed and vapor-laden, coming in contact with the strip of colder water between the latter and the coast.

Residents of Florida are also at long intervals treated to sudden and unexpected cold snaps which set the weather-prophets in a pother. It is said that during the anti-cyclone of 1835 the temperature at St. Augustine dropped to 7° F. Notable cold waves of late years occurred in 1886 and 1897 when the frost-line was forced many leagues south of its usual habitat, causing wide-spread amazement to the old inhabitants and great injury to the orange industry.

This enumeration quite completes the list of objections to the Florida winter weather. The tourist or health-seeker from the North, in search of sunny skies and a soft, genial atmosphere, will hardly fail to find them here in abundance, and the days when he is kept indoors by atmospheric conditions cut but a small figure in the bright and cheery vista from the late autumn to the early spring. Nor must it be taken for granted that the period of summer is unendurable in the peninsula. Many of the new and attractive towns in the Florida uplands, notably in Orange and adjacent counties, have large numbers of permanent northern residents who have chosen to make their homes here all the year round. The summers are undoubtedly long and warm, but the reports of the weather bureau show that many points along our northern frontier present higher thermometric ranges during July and August than are observed at Winter Park, Ormond, and other localities along the lake plateau. With the Atlantic on the east and the Gulf on the west and south, the temperature of the peninsula is appreciably modified by the seabreezes which, by favoring evaporation, convert much of the sensible into latent heat, producing an undoubted cooling or refrigerating effect and, at the same time, serving to eliminate much of the normal humidity of the air.

Malarial fevers unquestionably prevail in certain marshy districts of the State, and their presence has acted as a detriment to the fair fame of the entire peninsula as a resort for health-seekers. When carefully sifted, however, it will be found that the reports concerning these disorders contain but few grains of actual fact. It would appear that many sections of the State have always been free from this scourge, and in others, where it has been wont to flourish, it is apparently declining, both in frequency and severity, the old-fashioned algid and congestive types having practically disappeared. The writer is informed by Dr. Seagears, of the Alcazar Hotel that the recurrent chills observed among native Floridians about St. Augustine, which are invariably diagnosticated as malarial in character, fail to show the presence of the specific plasmodium on microscopical examination. He states that the topographical and soil conditions about St. Augustine are distinctly antagonistic to the propagation of malaria. The medical statistics of the United States Army show that the ratio of deaths from remittent fever has been less among troops stationed in Florida than in any other section of the country. If the writer may cite his own experience in this connection, he would say that of the not inconsiderable number of his own patients whom he has had occasion to refer to the peninsula during the last fifteen or twenty years not one has ever contracted any form of malarial disorder. The decline of these affections is doubtless due to improved drainage in a few localities, although some physicians attribute it to the increased cultivation of orange-trees. Tomasi Crudeli, in his address before the Copenhagen Medical Congress, pointed out that the cultivation of the orange and other members of the citrus family had apparently been influential in the elimination of malaria in certain districts in Southern Italy and Northern Africa.[1]

The writer is informed by physicians in different sections of the State that diphtheria is practically unknown, while such exanthemata as measles and scarlet fever are exceedingly mild in their manifestations. These statements appear to be con-

[1] According to my friend, Dr. Manges, Italian physicians have long believed in the virtue of lemon juice as an adjuvant to quinine in the treatment of malaria.

firmed by mortality statistics. According to the United States Census returns for 1890, the latest at hand, the annual mortality-rate of the State for all diseases was 10.50 per 1000 of population. It may be interesting to notice in this connection the death-rate in several other States. As computed from the National Census Report of 1890 they are as follows: California, 14.65 per 1000 of inhabitants; Colorado, 13.23; Illinois, 13.88; Kentucky, 12.85; Maine, 15.19; Massachusetts, 20.15; Minnesota, 11.89; New Hampshire, 18.79; New Mexico, 16.24; New York, 20.53; North Carolina, 11.23; Pennsylvania, 13.98; Tennessee, 13.49; Texas, 11.84; Virginia, 14.03; and Wisconsin, 11.06 per 1000 of population.

Perhaps the most important consideration in this connection relates to the advantages of the climate of Florida as a resort for persons threatened with, or affected by pulmonary tuberculosis. Is the peninsula a proper region to which to refer such persons for the winter months? Let us again consult the mortality statistics of the National Census Bureau, those of 1890 being again chosen as the latest accessible. The death-rate from consumption for that year for the States above cited was as follows: California, 2.39 per 1000 of population; Colorado, 1.18; Illinois, 1.49; Kentucky, 1.90; Maine, 2.23; Massachusetts, 2.67; Minnesota, 1.17; New Hampshire, 1.93; New Mexico, 0.63; New York, 2.47; Pennsylvania, 1.46; Tennessee, 2.06; Texas, 0.92; Virginia, 1.84; and Wisconsin, 1.19. The phthisical death-rate for Florida was 0.96 per 1000 of population, or less than that of any other State excepting Texas and New Mexico and several of the new and thinly-settled States of the far Northwest. It will thus be seen that the conditions prevailing on the peninsula are not favorable to the development and spread of consumption. Deducting the small, but constant number of invalids from other States who die there every year, it is altogether probable that Florida would show a smaller mortality-rate from this cause than any of her sisters in the Union.

In his work on bacillary phthisis, Germain Sée divides the climates suitable for the treatment of consumption into three great classes, viz., (1) warm maritime climates; (2) high altitude climates; and (3) the climate of warm, low countries not maritime. He regards the first two as including all that is essential in the climatic treatment of phthisis. Without in any way decrying the value of certain elevated regions in consumption, it is the writer's opinion that the conditions in Florida embody all the advantages of warm maritime climates. As before mentioned these consist chiefly of mildness and steadiness, to which may be added an abundance of light and ozone and, in most localities, freedom from dust. It is further possible, as Germain Sée suggests, that the increased oxygen of low levels is unfavorable to the biological necessities of the bacillus and tends to abridge its activity.

According to Dr. J. C. Wilson, of Philadelphia, the peninsula presents four distinct strips of territory which differ from each other quite materially, climatically speaking. They are as follows: (1) The Atlantic seaboard; (2) the St. John's River region; (3) the elevated pine-lands forming the water-shed of the State, and (4) the Gulf coast. He favors the pine regions of the interior and the Gulf coast, as being comparatively free from the sudden changes of the east coast and from the enervating influences and possibilities of malaria of the St. John's River resorts.

After much careful study of this subject the present writer is of the opinion that the climatic variations in different sections of Florida are determined, not by meridians of longitude, but by parallels of latitude. Traversing the peninsula from east to west on any given line in what may be termed the health-resort belt between the 27th and 31st parallels, one finds but a slight departure from the general characteristics above outlined. There are, to be sure, a few malarial spots of which to be wary, and some resorts are undoubtedly much better off in the way of hotels, scenic attractions, etc., than others. There is, as Keating points out, no well-defined frost-line, but the 29th parallel marks as nearly as possible the boundary between the region of damaging frosts and that where frosts are too light to injure orange-, lemon- or lime-trees.

A most important consideration for the medical practitioner relates to the class of cases to be referred to Florida for climatic treatment. We can never predict with positiveness how any individual case will progress after the patient reaches the peninsula. Many persons go there every year on their own responsibility and often to their own detriment and to that of the standing of the region as a health resort. In the absence of positive statistical evidence bearing upon the subject of climatotherapy, we are obliged to depend to a great extent upon the general observations of physicians and of their patients. It is the writer's opinion, based upon experience gleaned from his own patients and those of other physicians, as well as from a careful study of the literature relating to the subject, that the following classes of persons may properly be referred to Florida for the winter months:

1. Cases of recurring bronchitis or winter cough. These patients enjoy fairly good health during the summer months, but with the advent of the first raw days of the Fall they begin to have bronchial irritation, attended as a rule by a dry, irritable cough and occasional paroxysms of wheezing and dyspnea. These cases are not phthisical, but they are liable to develop more or less pulmonary emphysema with the progress of two or three winters, to the permanent impairment of their respiratory capacity. They are but slightly amenable to drug treatment. A sojourn of two or three months in Florida during the depth of the northern winter usually results in material improvement, often in a permanent removal of the *materies morbi*.

2. A large and important class of cases, hereditary or otherwise, in which there is reason to ap-

prehend the development of tuberculosis, even though no actual signs of the disease have set in.

3. A majority of cases of early phthisis prior to the formation of cavities. Patients showing great debility or a severe degree of anemia should not be sent to a southern climate, nor should those in whom acute manifestations are present. As in other localities nearer home, cases in which the well-known symptoms of pulmonary tuberculosis have become prominent are not welcomed everywhere on the peninsula, but the writer knows of no patient who has failed to find comfortable quarters.

4. Cases of so-called fibrous phthisis or chronic interstitial pneumonia. This form of pulmonary trouble progresses very slowly and is liable to extend over a long period of years. It is not cured by the climate of Florida, but almost without exception patients receive great benefit from a sojourn of several months in that region.

5. There is a very large valetudinarian class, composed of old rheumatics, victims of subacute or chronic gout, asthmatics, and intractable cases of chronic rhinitis, pharyngitis, laryngitis, lumbago, neurasthenia, general debility, etc., who are vastly improved by a season amid the sunshine and flowers of the beautiful peninsula.

During recent years the hand of man has done much to improve and develop the great natural resources of Florida. Magnificent vestibuled express trains and safe and elegant steamers convey the northern visitor from New York to the peninsula in from thirty hours to three days. A network of well-constructed and well-managed railroads within the State limits have made all desirable sections easily accessible and have led to the development of hitherto relatively-unknown and unfrequented districts. The visitor will find a chain of palatial hotels along both the Atlantic and Gulf seaboards, while in all sections of the State numerous excellent smaller hotels and boarding-houses are at hand for those who wish to live less expensively. In many localities golfing may be indulged in, while cycling is practicable almost everywhere. Boating, bathing, fishing and shooting also add their attractions in many quarters of the peninsula. Some detailed facts relating to individual localities in Florida will be given in a subsequent article.

In the foregoing contribution the author has been aided by the writings of Blodgette, Crudeli, Eager, Keating, Sée, Solly, Wall and Wilson, and by personal communications from physicians in the State of Florida.

783 Madison Avenue.

THE CLIMATOLOGY OF NEURASTHENIA.[1]

By F. CAVARY PEARCE, M.D.,
OF PHILADELPHIA;
CLINICAL PROFESSOR OF NERVOUS DISEASES IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA

A MORE accurate knowledge than at present exists of the effect of climate upon the health of people in general, such a knowledge as may be gained from a conscientious study of the statistics of health of a locality, of death-rate, longevity, physique, capacity to rear a generous progeny, etc., is extremely desirable. Such a knowledge would enable the physician to substitute for his present vague, "Go west," or "Be off to the woods," a definite statement of the meteorological conditions required by the case and of the existence of those conditions at some given spot, thus sending his patient off with a cheering and authoritative assurance of benefit to be confirmed by subsequent events, instead of submitting him, in a state of mental doubt and confusion, to climatic conditions which may after all be unsuited to his case and may therefore bring him back with bodily health unimproved, spirits depressed and pocket-book depleted. As a slight contribution toward the desired result, I purpose in this paper to discuss the climatic guarding of a special disease, neurasthenia.

In a lecture given before the Alumnæ of Nurses of the Presbyterian Hospital of Philadelphia, entitled "The Nurse in Travel, etc."[2] I endeavored to point out localities desirable to visit in moving about with a nervous invalid or convalescent, and the information conveyed in that lecture, although of a general character has proved of practical advantage to several members of the class addressed.

I shall present to-day more particularly data gained largely from personal observation in this disease. In the first place, I wish it to be understood that I consider neurasthenia essentially a nutritional malady of the central nervous system and believe that, while for successful treatment of it we must look back to the heredity, to both predisposing and exciting causes, which we need not rehearse here, we must seek in the therapeusis to eliminate *all* etiological factors. After all this very necessary detail is dealt with carefully, the treatment of the serious disorder in question must be put upon a nutritional basis. A study of the uric-acid elimination[3] by the kidneys extending over a half dozen years proves this basis beyond doubt to my mind.

The diagnosis must be made between hysteria *per se* and neurasthenia or the latter with a hysterical complication. It must be conceded that the hybrid case is more difficult to direct for the recovery of the patient than is any other neural disease. In well-established neurasthenia *per se* the partial or complete rest-cure alone will win out promptly. Upon how much of hysteria there is in the case and upon the physical condition of the patient should depend resort to other therapeutic measures, suggestion paramount among them.

It is in dealing with convalescents from neurasthenia, with incipient cases, or with those in danger of a recurrence, that the climatology of neurasthenia is especially important.

To speak generally, there are two extremes to be avoided by the neurasthenic invalid, namely,

[3] American Journal of Insanity, Vol. LVII., No. 1, 1900. "Further Laboratory Studies on Uric Acid in Neurasthenia and on Autointoxication in Nervous Disease."

a low, windy, treeless country and one characterized by constantly quiet atmosphere, high altitude (above 2000 feet), with low atmospheric pressure. An illustration of the former condition is found at Portland, Oregon, where I found neurasthenia very prevalent. In the higher parts of Southern California and New Mexico, on the other hand, the opposite extreme exists, and sufferers from "nervousness" frequently have to leave the country for a time in order to obtain relief. One of my own patients, a woman of culture and of strong physique, but neurasthenic from prolonged nursing of a case of phthisis in her husband, suffered constant relapses until she left California, whither she had gone for the sake of her husband's health. An outing at Buzzard's Bay, Mass., last summer, has quite restored her to health. The injunction I make in her case for remaining nervously well, is to sell out her ranch in the West and come to a lower country of more flora, of gentler breezes carrying a semisaturation of salt air so stimulating to metabolism and nourishment of the central nervous system.

The suitability of any given district, whether furnishing sea or mountain air, for the treatment of nervous exhaustion states, depends then upon altitude, that is, barometric pressure, upon the character, temperature and evenness of prevailing winds, upon the nature of the subsoil, gravelly loam being most desirable, upon abundance of sunshine, and, finally, in a lesser but still important degree, upon idiosyncrasy.

Boston is not a suitable locality for neurasthenics, and yet I know a neurasthenic man who was made worse by going from there to the Adirondacks at an altitude of 2000 feet in a very damp part of that wilderness. He was advised by me to seek the "mean" and recovered. Another man, an overworked publisher of New York, aged fifty-two years, having sought health in many parts of the country, went into camp in the Adirondacks where I saw him in September, 1898. The camp was located at an altitude of 1500 feet on a beautiful pond, surrounded by the second growth of trees and much bush which latter held the heavy dews until late in the morning. In all other respects this camp was ideal for a summer outing; but it was bad for a neurasthenic for the reasons already given. At the end of ten days, this man began to have "mental restlessness"; the pressure in his head "grew alarming to him"; he could stand no exertion whatever. He was not hysterical. Palpitation of the heart soon followed, with, at the end of a fortnight, well-established and persistent insomnia. I advised his going down to well-protected Watch Hill, Rhode Island. Upon doing so he reported immediate improvement and since then has gone to this delightful coast line to the recovery of full health.

With the lowered barometric pressure at Anaconda, Montana (altitude 5000 ft.), Dr. James F. Spillman of that place informs me that there is prevalent much neurasthenia, and that general nervousness complicates many diseases he has to treat.

In neurasthenia, localities where heavy storms are prevalent are to be avoided, if possible. Such storms in the temperate zone of the United States are, as a rule, due to the movement of northerly winds from the lake region overrunning the Hudson valley toward the Atlantic seaboard at some particular locality, as in the very severe storm we experienced on August 3d last, and which spread from Maine to Virginia. It is said that thunder storms are unknown at Bath, Georgia. Further study of the effect of such a locality upon neurasthenics should be made.

The Maine country about Rangeley Lakes is almost ideal for neurasthenic patients, having an altitude of 600 to 1000 feet, with a rare combination of sea-(salt-) and pine-(ozone-) laden atmosphere conjoined with plenty of sunshine, all mildly stimulating meteorological conditions. Next in order in America I should place the inland country of New Brunswick and of Nova Scotia, away from the fogs of the coast. Third in order comes that delightful, gravelly and stony country in the United States and Canada, the Great Lake region of Ontario, Wisconsin and Michigan, stretching east to the beautiful group of the Muskoka Lakes and about Lakes Simcoe and Nippissing.

I give herewith a table of altitudes of some places near at hand where it is desirable to send the neurasthenic convalescent.

TABLE OF ALTITUDES.

Locality.	Altitude.
1. Blue Mountain Lake, Adirondacks	2000 feet
2. Lake Massawepie, Adirondacks	1400 "
3. Schroon Lake, Adirondacks	830 "
4. Lake Chautauqua, New York	2103 "
5. Lake Canandaigua, New York	688 "
6. Great Lakes	500 to 680 "
7. Lake George	310 "
8. District about Rangeley Lakes, Maine	800 to 1000 "
9. Lake Hopatcong, New Jersey	926 "
10. Harvey's Lake, Pennsylvania (the largest body of fresh water in that State)	1250 "

I close with a brief summary of the conclusions reached in this paper.

It is almost axiomatic that an altitude of over 2000 feet is unsuitable for the neurasthenically-disposed or convalescent patient. Any very "stimulating" climate should be avoided. Other conditions to be avoided are as follows: Districts menaced by high winds and frequent fogs; cloudy, saturated atmospheres with but slight movements of air-currents; low country (sea level) with continuous, non-varying, although moderate heat, as where the effects of the Gulf Stream is strongly felt. Thus the Bermuda Islands and Florida are enervating localities.

Ideal conditions for the neurasthenic include sea-air in a well-wooded country, far enough from the coast to avoid its fogs. A sea-voyage is, as a rule, an excellent preliminary to other climatic measures. Provided the voyage is not stormy it acts both psychically and physically in soothing the nervous system.

In order to obtain the full benefit of correct climatic conditions the patient must have good food. Without this important adjunct the desirable climatic change may be entirely defeated in its effect on the patient.

1407 Locust Street.

THE TONSILS AS PORTALS OF INFECTION.*

By JULIUS ULLMAN, M.D.,
OF BUFFALO, N. Y.;
INSTRUCTOR IN CLINICAL MEDICINE IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO; PHYSICIAN TO THE GERMAN HOSPITAL.

Waldeyer's tonsilar ring consists of (1) the pharyngeal or Luschka's tonsil, (2) the tubal tonsils or cushions of the Eustachian tube, (3) the faucial or true tonsil, and (4) the glossic tonsil. These structures belong to the lymphatic apparatus and have been compared to Peyer's patches in the intestinal tract. The faucial tonsils are oval-shaped nodes the size of hazel-nuts. In health they should be barely seen. Each tonsil is imbedded in faucial peritonsillar tissue. On the surface are from eight to eighteen openings, the entrance of crypts (lacunar spaces). The crypts are lined with mucous membrane and are apt to become filled with a thick, yellowish secretion (fat molecules, loosened epithelium, lymph-corpuscles, granular matter, cholesterin crystals, etc.).

The pharyngeal tonsils differ from the tonsillar tissue in that they have no crypts, but an abundance of irregular spaces between them in which dirt and discharges are held (Dawbarn).[1]

The tonsils have a very large blood-supply and the lymph-sinuses communicate freely with the lymphatics of the mouth, pharynx and deep cervical lymph-nodes (Ashby & Wright).[2]

One of the functions of the tonsils is the formation of leucocytes, which, according to Stöhr[3], find their way into the salivary secretion by an amœboid movement. Kingston Fox[4] says that the tonsils have an absorbing function, *i. e.*, the absorption of a superabundance of saliva. It is also claimed that they produce a secretion which lubricates the food, but, containing no mucous glands, they do not secrete in the sense of glandular secretion, and Hodenpyl[5] relegates this secretory function to the adjacent tissue and not to the tonsil itself.

Killian[6] believes that the contained leucocytes have the power to destroy micro-organisms. Labbe[7] also thinks that the follicles by an extension of the epithelial surfaces are a means of defence against bacterial infection, but Goodale[8] has lately claimed that the leucocytes present are of the mononuclear variety. The lymphocytes are not phagocytes and cannot therefore be regarded in this light. Goodale also claims that absorption exists in the tonsil and takes place through the mucosa of the crypts, whereas Hodenpyl in a series of experiments maintains that the epithelium of the crypts prevents absorption, but that substances finding their way beneath the epithelium may be taken up rapidly by the lymphatics, and this he explains frequently to be the case on account of the very thin layers of epithelium and its constant rarefaction. He also showed that soluble and insoluble materials in the substance of the tonsil remain in the tissue or are carried by the lymphatics to the other parts of the body.

As to the capability of the absorption of micro-organisms by the tonsil, Ribbert[9] found that the bacillus of diphtheria in rabbits is not absorbed by the buccal mucous membrane except in the tonsils in which the epithelium is desquamated. Schlenker,[10] having found cases of tuberculosis of cervical nodes in which the tonsils either were or were not diseased, states that in the latter case the tubercle bacilli must have wandered through the tonsil. Buschke[11] also concludes that the tonsils are portals for pus-producing organisms. They do not enter the system without affecting the tonsils, be it ever so lightly, so that Pluder[12] contends that tonsillar protection to the invasion of disease is very small, as the tonsils are frequently diseased and hence portals for the entrance of bacteria. Schech[13] also makes the statement that in the adult the tonsil is seldom normal.

From the foregoing remarks it is seen that the function of the healthy tonsil is but little understood. Certain it is that, being of the lymphatic system, they have to do with the formation of leucocytes of a mononuclear variety and that these leucocytes have little phagocytic action.

The tonsils may protect the system by a filtration of micro-organisms and an attenuation of their virulence, thereby giving a certain amount of immunity in health. They are, however, very susceptible to the invasion of bacteria and to infection. Because of their position the various forms of aërial poisons are prone to be aspirated and to lodge here; food substances, with their poisons, bacteria, etc., may also find lodgment coming in contact during the deglutition act. The tonsils afford places of lodgment because of their irregularity of contour, the presence of lacunar spaces, the rarefaction of the epithelium lining the crypts (Hodenpyl) and the exudation of the epithelium which leave places of denudation and afford the *locus minoris resistentiae* to the various organisms. The tonsils are therefore constantly exposed to pathogenic organisms contained in liquid, air and food. They are also exposed to the bacteria constantly to be found in the nasal and buccal cavities; as occurring in the nose, Eisenberg[14] mentions staphylococcus pyogenes aureus, streptococcus erysipelatus, bacillus foetidus ozaenæ, Friedlander's pneumobacillus, rhinoscleroma bacillus, bacillus mallei and bacillus smaragdinus foetidus; the same author mentions in buccal secretion pyogenic bacteria, diplococcus pneumoniæ, diphtheria bacillus, tubercle bacillus, and many pyogenic organisms in and about the teeth, as described by Miller, such as bacterium gingivæ pyogenes, bacillus dentalis viridans, also fungi-like actinomycosis and aspergillus fumigatus. These bacteria require heat, moisture and a good soil for their growth. They obtain the two former conditions and so far as soil or proper media is concerned, it requires but a loss in the immunity of the individual or host to make active the pathogenic organisms always present and to induce infection.

*Read before the New York State Medical Association, October 17, 1900, and before the Buffalo Academy of Medicine, October 22, 1900.

Having shown that the tonsils are easily accessible to micro-organisms and that they are constantly exposed to their action, it requires the clinical proof that such takes place.

The tonsil, especially the faucial tonsil, often becomes inflamed through the agent of pyogenic organisms, lodging in the lacunar spaces. The epithelium of the mucosa, because of the engorgement of the vessels, is deprived of its nutrition and exposed to the poisonous substances produced by the organisms; it becomes swollen, clouded and dies; in other words, is converted into pus. As a consequence of this metabolic change and the secretion of the bacteria, toxic substances are formed which, being absorbed, produce constitutional symptoms, namely, malaise, headache, bone-ache, chills, elevation of temperature, bounding and frequent pulse, etc.

Among the organisms demonstrated in the lacunæ in tonsillitis are the streptococci, staphylococci albus and aureus, Fraenkel's pneumococcus and Friedlander's pneumobacillus.

As to the predisposition for an attack of tonsillitis may be mentioned the relation existing between the hyperplasia of either the lingual or pharyngeal tonsil in young children. The adenoids through their obstruction induce mouth-breathing and a lowering of the vital resistance, rendering an assault of bacteria the more successful. There is a constant aspiration of pathogenic bacteria to the faucial tonsil and the individual is more susceptible because of a lowering of vital resistance.

One attack of tonsillitis predisposes to another and, as a result, the crypts are deeper, the fibrous tissue and lymphoid tissue are increased, and the vessel-walls are sclerosed. Depending on the increase of fibrous tissue will depend whether or not the hypertrophied tonsil is hard or soft. It is this tonsil which is *par excellence* the principal portal for infection for here we have lost in the normal function, and the parts are dry, the lacunar spaces widely open and filled with bacteria, and the antigermicidal secretion of the lymphoid cells, if any, is *nil*. But it is nevertheless not my intention to state this without some qualification, for in many cases of infection via the tonsils, they are apparently little affected.

Jessen[15] emphasizes the fact that a tonsil with normal appearance may contain foci of suppuration. Many cases are reported which show severe infection following an attack of tonsillitis. This infection may be classified into (1) a toxemia, as diphtheria; (2) a septicemia, and (3) a septicopyemia. The involvement of the faucial tonsil in a great majority of cases in diphtheria and its toxic effects (paralysis of muscles of deglutition and heart) need not be emphasized in this paper.

If the organisms producing a tonsillitis are pyogenic and enter the tissue a simple lacunar tonsillitis becomes septic by the formation of a tonsillar abscess or the adjacent peritonsillar tissue is affected by contiguity with the formation of a peritonsillar abscess, Ludwig's angina or a retropharyngeal abscess. In this process the cervical lymph-nodes are also affected and many constitutional complications, pyemic in character, may follow which are severe and often fatal.

Spaet[16] describes two fatal cases of general septicopyemia in which he thinks the port of entrance to have been a catarrhal affection of the tonsil. Treitel[17] speaks of the importance of tonsillar abscess as a port of entry of general sepsis. Jessen[15] reports four very interesting cases of sepsis following tonsillitis. (1) Man with exudation on the tonsils followed by constitutional symptoms, pain in extremities, stupor followed by an erythematous eruption, the erythema and pains in joints disappearing in eight days with an irregular fever-curve. Pure cultures of staphylococci and streptococci were obtained from the tonsils, but none in the blood. (2) Woman who came to hospital in a comatose condition and died from uremic convulsions. The autopsy showed the superficial tonsil smooth, but on section many abscesses were found. The kidneys were filled with hemorrhagic areas and abscesses. (3) Chlorotic girl with angina of left tonsil from which pure culture of streptococci were obtained. The angina was followed in twelve days by a wandering pneumonia (only streptococci in sputum, no pneumococci or influenza bacilli), then by a pericarditis, pleuritis and nephritic irritation evidenced by the presence of albumin and casts in the urine. (4) Girl with angina followed by a pericarditis, double pneumonia and general sepsis. Author recovered postmortem the same organisms obtained in culture from the tonsil in all the organs. In this case the tonsil superficially showed little or nothing, but on section pus was found.

Du Mesnil de Rochemont[18] describes an epidemic of angina in a hospital in Altona, thereby demonstrating the contagiousness of ordinary angina. There were 18 cases out of 67 patients, or 23 per cent., affected. In the following two months, 19 were added. The angina varied from a catarrhal-follicular form to a gangrenous exudate and swelling of the peritonsillar tissue. Streptococci and staphylococci were found in culture. As complications the author noted acute articular rheumatism three times and once each nephritis, pericarditis, endocarditis and myocardial weakness. Dr. William Bergtold, of Denver, Colorado, in a personal communication, has described to me an epidemic of sore throats occurring in Denver in November, 1898. He believes there must have been a very large number of cases (20,000). The disease was very contagious. There was only a slight sore throat, the pharynx and tonsil had a purplish-blue look, almost edematous, with, in some cases, an occasional patch of membrane. The symptoms were much those of influenza. Dr. Bergtold in the cases examined by him obtained streptococci. In one case observed by him (Dr. Joslyn) there were two relapses, in the last of which the patient developed a bronchopneumonia, pericarditis, ulcerative endocarditis and died. He believes there were many other cases of sepsis due to the angina which, unfortunately, are not reported.

Hiddeaus[1] reports a case of tonsillitis due to staphylococci pyogenes aureus followed by a pleuritis in the exudate of which he found the same organisms. Hanot[20] also reports pleuritis following streptococci angina, as does Richardière.[21] Heinze[22] in 1261 cases of angina examined by him at the Leipzig clinic found 38 cases of nephritis, some of which were protracted and one of which died.

Fraenkel[4] records ten cases of leucemia, the course of each seeming to point to an infection and the early involvement of the cervical lymphatics suggesting an invasion from the pharynx or tonsils. F. G. Wood[24] in a report of cases of Hodgkin's disease, states that in one case observed by him the infective agent gained entrance through the tonsil.

Thomas[25] reports the case of a child, seventeen months of age, attacked with tonsillitis sinistra, swelling of cervical and submaxillary glands. On the third day otitis media of left side developed, then retropharyngeal abscess of right side with pharyngitis and acute suppuration of nares and nasopharynx, then a erythema scarlatinoid, enteritis, pneumonic infarcts. On the forty-first day of disease the child died of meningitis. Cultures from the pus of the ear showed streptococci and staphylococci pyogenes aureus. The author regarded the disease as a streptococcus infection.

Simonini[26] records an epidemic of five cases of infantile paralysis; as to its origin he believes it related to rheumatism and hence to tonsillitis. Packard[27] says that angina may be the cause of many unexplained systemic cord diseases. K. Dehio[28] reports a septic maculopapular erythema following follicular tonsillitis.

Through the courtesy of Dr. Grover Wende I saw a case of giant urticaria following an ulcerative tonsillitis in both tonsils. The case simulated somewhat scarlatina with angina. Cultures of streptococci were obtained from the tonsils. This case rather conforms to the later theory of urticaria which speaks of it as due to toxic substances in the blood. Cases of urticaria following tonsillitis are described by Rosenthal,[29] Boeck,[30] and others. Bull[31] described purpura following tonsillitis. F. A. Packard[32] reported five cases of endocarditis which were preceded by an attack of tonsillitis, in three of which it was definitely known that the heart was normal before the attack of angina. In the other two cases the previous condition of the heart was not known from personal observation, but there was nothing in the past history referable to the heart.

Emil Mayer[15] also relates the case of a man in whom the diagnosis was made of an endocarditis following tonsillar infection. Endocarditis frequently follows many of the infections and contagions diseases. It is an early complication of sepsis in which it may occur as a simple or ulcerative form. It follows or accompanies acute articular rheumatism in 60 to 70 per cent. of cases.

It has been shown in cases cited above that sepsis may be produced through the tonsil. So far as concerns the exanthemata, it is well known that a majority of them have an early angina, witness the severe throat lesions in scarlet fever, so difficult to differentiate from a true diphtheria. Abbott[34] although he says it is not generally accepted, states "that the clinical manifestations of the disease (scarlet fever), as well as the anatomical lesions, except those in the throat, are the result of the absorption of toxins, produced by the streptococci located in the diseased tonsils."

Class[35] described a diplococcus scarlatinæ as a cause of scarlet fever and gives a synopsis of 300 cases, showing the presence of this organism in the throats; Gradwohl[36] in seven cases confirms Class's findings and speaks of the contagiousness of inoculated mice to others not so inoculated in the same cage. Baginsky and Sommerfeld[37] from a study of 42 cases of scarlet fever obtained, in the angina, pure cultures of streptococci sometimes accompanied by other cocci and in all fatal cases (42) examined by them the organisms were found in the blood and bone marrow, from which they conclude that the streptococcus is constant in scarlet fever.

Class,[38] in a later contribution, differs from the above-named authors in the morphology of the organism, claiming that it is a diplococcus and not a streptococcus. He speaks for priority in discovering it and shows that the organism is constantly present in scarlet fever, that it is a pathological organism for mice, swine and guinea-pigs, that scarlet fever can be produced in the white swine by the diplococcus, that the pathological changes in the organs caused by the diplococcus scarlatinæ resemble those of scarlet fever, that the disease produced is of a contagious character, that the influence of the blood of a scarlet-fever patient on plate-culture inhibited its growth, and that the organism was found in the throat secretions of scarlet-fever patients. The author's claims accord to Koch's law, but further cumulative and confirmatory evidence can only give to this organism its place as the specific organism of this disease. One proof of the tonsillar affection in this disease, as in diphtheria, is the common early involvement of the cervical lymph-nodes.

Trousseau[39] in his writings speaks of rheumatism as being ushered in by a sore throat. Buss[40] emphasizes the relation between angina and acute articular rheumatism. The examinations showed the same micro-organisms for both, namely, pyogenic cocci, and he concludes that in many cases the port of entry for rheumatism is in the tonsils. Stirling[41] also reports five cases of follicular or catarrhal tonsillitis immediately followed by acute articular rheumatism and draws the same conclusions as does Buss.

G. Bloch[42] discusses the etiology of rheumatism from a clinical standpoint, *i. e.*, the relation existing between angina and rheumatism. It may follow any form of angina from a light catarrhal to a deeply lacunar, from a herpetic tonsillitis to a peritonsillar abscess. From 20 to 80 per cent. of rheumatic cases follow an angina, the disease of the tonsil giving a direct cause for a mild attenuated pyemia. Sahli obtained the staphylococcus

pyogenes citreus from the blood, synovial membrane of joints and exudate of endo- and pericarditis in rheumatism. Singer reports having found the staphylococcus pyogenes albus in urine and blood, and later the staphylococci and streptococci. This author[43] also speaks of the close relationship between acute articular rheumatism and osteomyelitis and looks upon the latter as a peculiar form of pyemia, in youthful individuals staphylococcus occurring in the form of osteomyelitis, in older individuals as acute articular rheumatism.

Bertram Abraham[44] found in the exudation of so-called sore throats a staphylococcus and streptococcus. These germs may also be found in blood and urine. The presence of the germs in the joint effusion seems not only to point to their being the actual cause of the disease, but to the strong probability that they enter the system by way of the tonsil. Achalme[45] described a bacillus found in the blood in rheumatism which is anaerobic and whose growth is facilitated by lactic acid and prevented by salicylates.

J. Thiroloix,[46] in a case of acute articular rheumatism complicated with pericarditis, double pleuritis and pulmonary congestion, derived from the pleural exudate and venous blood a diplococcus and bacilli arranged in chains with four to twelve flagellæ. In animals inoculated with the bacillus the author could induce similar pathological changes, as in acute articular rheumatism, with the exception of changes in the joints.

In the discussion on acute articular rheumatism at the last meeting of the American Medical Association, Packard, Musser, Anders, Stockton and Favill regarded acute articular rheumatism as an infectious disease. As to the specific organism, if any one species of organism may be mentioned, further investigation will have to be made. One thing is certain—that the port of entry to the variety of organisms having to do etiologically in a majority of cases of acute articular rheumatism is the tonsillar tissue. Packard,[27] however, quotes several authors showing beside the tonsils the port of entry of germs inducing acute articular rheumatism to have been phlegmon, otitis media, dysentery, bronchiectasis, gum-boil, vaccination, etc.

There is a close relation existing between tonsillitic rheumatism, endocarditis and chorea. MacLagan[47] states that rheumatism is essentially a disease of the motor apparatus and that chorea is a disease of the motor centers. Chorea affects those having a history of present or prior rheumatic attack with or without a heart affection and there are cases, as, for instance, those following shock in which there is a family history of rheumatism.

Bertram Abraham found in 243 cases of chorea that 53.4 had a family history of sore throat.

Collins and Abrahamson,[48] in a series of one hundred cases examined, state their conviction of a definite relation between chorea and rheumatism, but do not believe in the infectious theory, claiming that the recurrences and relapses speak against it; but Triboulet,[49] in 1892, described a coccus obtained from the blood in canine chorea and later found cocci in the blood of a case suffering from chorea and cerebral rheumatism, so Mircoli[50] believes chorea rheumatica to be an infectious process allied to several forms of bacteria of which the staphylococci are the more common, whereas Guiderossi and Genzetti[51] show that staphylococci may be in the circulation in Sydenham's chorea without attributing to them the cause of the nervous disease. They regard the presence of the organisms as a secondary infection and do not believe them to be a primary cause.

Joseph H. Abraham[52] reports a case of tonsillitis followed by endocarditis, articular symptoms and chorea, and Packard also reports cases of chorea following tonsillitis.

I recall the following case: L. W., aged thirteen years, schoolgirl. One sister died of dropsy, mother is rheumatic (I have since attended her for an attack of acute articular rheumatism); had diseases of childhood; one year ago was sick seven weeks with a severe attack of acute articular rheumatism, which was followed by choreic movements and heart trouble. Patient does not learn well at school. Has lost weight, has no appetite, complains of shortness of breath on exertion. Has chilly sensations, bowels irregular and complains of sore throat. The girl is anemic, tongue coated; she is a mouth-breather. On pharyngeal examination I find both tonsils markedly hypertrophied and the lacunar spaces open. Slight choreic movements are noted. Lungs negative; heart gives a soft systolic bruit transmitted to the axilla.

Because of the previous family history and condition of the tonsils, I advised their removal, fearing another attack of rheumatism. The patient took it under consideration, but in three days I was called to her home. The dwelling was old and the floor of the bedroom was lower than the ground outside. The floor was cold and damp as there was no cellar. The patient was in bed and appeared to be in great pain and distress. Her temperature was 102.4° F., pulse 110, respiration 32; anemia marked; tongue coated, breathing labored. The heart sound gave the systolic bruit at apex and in addition hemic bruits at the base. Lungs negative. There was a polyarthritis involving the phalanges and metacarpal articulations of the left hand, wrist, and elbow, and also both feet and ankles. There was redness, heat and great pain rendering examination of the patient difficult.

The patient was sent to the General Hospital, where, through the courtesy of Dr. Stockton I further observed the case. Under large doses of sodium salicylate, one to two grams, local applications of heat, and iron and strychnine, the patient soon improved. The heart lesions and some choreic movements still remained when she was discharged in March, 1900. The patient again came to my office in September, 1900, complaining of sore throat, headache and severe pains in the extremities. I removed both tonsils, and since then she has been doing well. The heart lesion

and slight choreic movements persist. Histological examination of the tonsils removed showed an exudation and denudation in place of the epithelium lining the crypts with a great increase both in the lymphoid and fibrous tissue.

The lesions of typhoid fever are usually located in Peyer's patches and the solitary follicles of the intestinal tract, but Banti,[53] Vaillard,[54] Karlinski,[55] Vincent,[56] Guarmieri,[57] Kühnau,[58] Flexner & Harris,[59] Cheadle,[60] Chiari and Krauss,[61] Lartigau,[62] Ophills,[63] McPhedran,[64] and others, have reported true cases of typhoid fever in which no intestinal lesions were discovered postmortem.

Capillari[65] reports five cases of typhoid fever in an epidemic in which the disease set in by a tonsillar growth. He gives similar observations by Coradischi and finds a like infection for tonsils and Peyer's patches as not unlikely on account of the similarity of structure in the tissues. He quotes Lucatello who found bacillus of typhoid fever in laryngitis.

In this connection may be mentioned a case reported to me by Dr. Allen A. Jones. The patient, a girl, aged twenty years, went to a trolley party and on the following day complained of a sore throat. Her temperature was 105.8° F. and there were symptoms of fever. Examination of throat showed on the left tonsil an acute follicular tonsillitis; cultures showed staphylococci in pure culture.

On the third day the soft palate was edematous, the right tonsil showed follicular tonsillitis; temperature 104° F. Despite cold packs and antipyretics the temperature for five days was never below 103.5° F. On the fifth day delirium was present and a Widal examination was negative; two days later it was positive.

The blood showed a leucopenia; erythrocytes 4,700,000, leucocytes 6800; hemoglobin 80 per cent.

Was this a mixed infection through the tonsil or did the pyogenic infection lower the resistance to a secondary typhoidal infection?

In view of the fact it leads necessarily to the suggestion that in some few cases the portal of entry for the Eberth bacillus may be the tonsillar tissue.

It is worthy of notice that in the oropharyngeal cavity, next to the lips and tongue, the tonsils are seats of initial lesions of syphilis, the open mouths of the crypts presenting a favorable lodgment for the virus.

Jessen[15] believes, as does Zarniko,[66] that in many cases, scrofulosis represents nothing more or less than a general infection from the tonsil, more especially the pharyngeal tonsil. Jessen quotes four very interesting cases which show that after the removal of adenoids in young children, the symptoms of scrofulosis subsided. As scrofulosis is blended with tuberculous adenitis of cervical and bronchial lymph-nodes, the cause of a sudden eruption of a latent tuberculosis into acute phthisis, miliary tuberculosis or tuberculous cerebral meningitis, is at hand.

This leads to the suggestion that the tonsillar tissue may oftener than credited be the port of entrance of tubercle bacilli into the general system.

Pluder and Fischer[67] demonstrated the presence of tubercle bacilli in the tonsil limited to the mucosa in five out of thirty-two cases examined and believe this condition represents a latent primary form of the disease. They quote Lermoyez who found the tonsils tuberculous twice in thirty-two cases examined, Gottstein four times in thirty-three cases examined, and Brindel eight in sixty-four cases examined.

Friedman,[68] in a careful histological examination of one hundred and forty-five cases in fifty-four of which the tonsils were removed during life and in ninety-one on postmortem, from young children, states that tonsillar tuberculosis occurs as often primarily through infectious feeding as secondarily from the sputum, and he concludes that the tonsils especially in small children, are not without importance as portals for tuberculous infection.

To me the following case illustrates the relation of tonsillar disease and pulmonary tuberculosis: S. A., aged twenty-one years, barber; has been under observation for two years, never, however, for any pulmonary complaint. In several examinations of the chest made during that time no evidence of pulmonary disease was noted. The family history gives no tuberculous history. In August the patient came to me complaining of malaise, weakness, cough and night-sweats. There had been hemoptysis a number of times a few days prior to his visit, which the patient interpreted as from his stomach.

Physical examination reveals along the left supra- and infraclavicular space harsh breathing, subcrepitant râles and broncophony; in the mammary region of same side, bronchovesicular breathing and friction râles; at the right apex increased vocal fremitus a few râles; at the left and right suprascapular region increased vocal transmission, bronchial breathing, and fine crepitation. The cervical lymph-nodes were enlarged. Examination of the sputum showed tubercle bacilli. On examination of the pharynx the right tonsil is remarkedly hypertrophied. It was removed, not in the hopes of offering anything in the way of treatment, but for histological examination. No tubercle could be detected, but the lymphoid tissue was increased as was the connective tissue stroma; the epithelium of crypts was also increased.

Although no tubercle can be detected in the sections thus far examined, I am nevertheless convinced that, because of the enlargement of the cervical lymph-nodes, the tonsil is a portal of entry for the tubercle bacillus.

In conclusion it has been shown:

1. That the normal tonsil has a physiological function, probably protective to the organism.

2. That being in itself often diseased, the physiological function of the tonsil is impaired and that instead of being protective, it is the nidus for the growth and distribution of pathogenic organisms

and their poisonous products into the system.

3. That many grave and fatal general infections have their origin in the tonsils.

4. That, if the exanthemata, especially scarlatina, are of bacterial origin, the tonsil acts in part as port of entry.

5. That acute articular rheumatism and the diseases often associated with it, endocarditis and chorea, in a great majority of cases are due to the action of attenuated bacteria, their toxins or both entering the general system through a diseased tonsil.

6. That in rare cases of typhoid fever in which no intestinal ulcerations can be demonstrated, the similarity of the tonsillar tissue and Peyer's patches suggests the portal of entry of the Eberth bacillus into the tonsil.

7. That scrofulosis is often associated with diseased tonsillar tissue and that the tubercle bacillus often enters the system via the tonsils.

8. That the tonsil is too little examined at necropsy and that much light might be shed on fevers of uncertain origins by bacteriological and histological examination of it.

MEDICAL PROGRESS.

Deleterious Effects from the Use of Coffee.—Probably too little attention is paid to the functional disorders of the nervous and digestive systems, induced by the habitual overindulgence in the use of coffee. W. M. LESZYNSKY (*Med. Rec.*, Jan. 12, 1901) believes that this beverage is the cause of a large number of the neurasthenic symptoms so common among the American people. One-third of all coffee is consumed by Americans and since its action is to excite the imagination and the memory and to augment the power of attention, it is reasonable to suppose that under the strain of overwork of our modern civilization many are induced to temporarily stimulate their mental faculties far beyond the capability of the individual. The symptom-complex usually noted is as follows: General nervousness, tremor, vertigo, restless sleep, cardiac palpitation, eructations of gas and constipation. The pupils are slightly dilated and the reflexes exaggerated. A severe case may be confounded with alcoholism. An important difference between the acute and chronic form is that when taken in large doses it causes extreme excitability, but in the chronic form which is the more common the toxemia manifests itself as a depressive form of neurasthenia A gradual reduction in the amount used is necessary and a substitution, if indicated, of some harmless beverage. As a sedative to the nervous system the following is recommended three times per day: Sod. Brom., gr. xv; Lig. Potas. Arsenitis., ♏ ij; Tinct. Gent. Comp., 3 ss; Ext. Kola Fld., ♏ xv. At the end of a few weeks, tonics such as quinine, iron and strychnine should be substituted.

Intestinal Flora of Sucklings.—H. TISSIER (*Thèse de Paris*, 1900) has very recently brought forward some interesting results of studies made in Professor Grancher's laboratory in

Paris. The conclusions reached are based on 19 clinical observations and many bacterial investigations. Briefly, the contents of this monographic article of 254 pages may be summed up as follows: The intestinal flora widely varies, depending on whether the infant is bottle-fed or nourished at the breast. In the breast-fed child, after an aseptic phase which lasts from ten to twenty hours, bacteria appear in the intestinal contents, cocci and bacilli; in the stools following the first feedings appear successively the bacillus putrificus coli and the bacillus bifidus. This infection appears to come from the mouth; the coli may come, however, from the anus. Toward the fourth day the flora becomes fairly constant—B. bifidus, B. coli, streptococcus, B. lactis aerogenes. In pathological stools there may be present in addition the diplococcus liquefaciens, B. anærobius perfœtens, and a streptococcus which looses its stain by Gram. In bottle-fed infants the B. acidophilus, B. exilis, enterococcus, B. coli, B. lactis ærogenes, B. bifidus, sarcinæ, etc., are often present. In the chronic gastro-intestinal infections of infants the diplococcus griseus liquefaciens, B. minutis, and members of the colon group are often found. The examination of the stools suffices to enable one to draw conclusions as to the method of feeding. In breast-fed children the fermentations are of little pathological significance. In bottle-fed infants digestion is incomplete and the intestinal contents richer in fermentable substances than when nourished at the breast. The determining cause of gastro-enteritides is almost always an infection; in a few instances the affection is purely toxic in character. The author does not recognize a primary endogenous infection. The relative immunity of the breast-fed child seems to depend (1) on the chemical condition of the intestine little favorable to the development of bacteria; (2) on the presence within the intestinal canal of the B. bifidus which inhibits the growth of the B. anærobius perfœtens, streptococcus intestini, B. coli and lactis ærogenes. The susceptibility of artificially-fed children depends (1) on the chemical state of the intestinal contents, richer in fermentable substances; (2) on the bacterial flora less resistant to the action of poisons, which contains varieties neutralizing the action of inhibiting organisms like the B. acidophilis, and other forms, resembling some varieties of sarcinæ.

Urethrotomia Interna.—B. GOLDBERG (*Deutsche Zeitsch. f. Chir.*, Nov., 1900) says that this operation should be done so that the incision is only on the upper wall of the urethra. The reasons are that mesially the urethra is most free from erectile tissue on its dorsum, hence hemorrhage is much less apt to be severe than when the other walls are cut. The only exception to this rule is that in the membranous urethra the venous plexus of Santorini is present over its dorsal aspect. When the pendulous urethra is the site of operation it should be drawn tense so as to make it easier to cut. The best instrument for all-round service is the Maisonneuve. The most careful antisepsis must be observed. All possible instruments must be boiled and others immersed for a long time in antiseptics. When the lumen of the stricture permits, urethral and vesical irrigation must be practised. In impassable occlusions urotropin is very serviceable in rendering the urine clean. The retention of a catheter for one or two days after the operation is of service. The prognosis of this operation as to fatalities is absolutely good; as to cures as favorable as possible, and as to infiltration of urine, infection and other complications considerably better than the external.

Tetany in Infancy.—JOHN L. MORSE (*Phila. Med. Jour.*, Jan. 5, 1900) considers briefly the character, the etiology and the frequency of the occurrence of tetany in infants and reports in detail seven cases of interest not only as examples of the condition, but also as throwing some light on its etiology. A summary of these cases shows that there was no common etiologic factor. Digestive disturbances occurred in all but one. In one case they seemed the only factor, while in two others they seemed the only important factor. In only one case were they apparently unimportant. Moderate signs of rickets were present in one case and slight signs in three others. Craniotabes was not present in any case. The gums were distended by teeth in two cases, and in one of these no other cause of tetany was evident, but in this case the condition of the gums remained unchanged after recovery. Influenza seemed to be the cause in one case and syphilis in another. In all except one case conditions were present which were evidently capable of causing toxic products. Morse concluded that tetany is due to the action of the toxic products of many diseaseed conditions on the nervous system, and, for this reason, says that treatment must be directed to the cure of the primary disease, to the prevention of the formation of toxic products, and to their elimination, if already formed. Symptomatic treatment is also important to relieve pain and discomfort, but should not be employed to the exclusion of the treatment of the causative condition.

Vaginal Caesarean Section.—A. DÖHRSSEN (*Archiv. f. Gynäk.*, Bd. 61, Hft. 3) reports another case of eclampsia in which the uterus was emptied quickly by the method which was first presented by him in 1896. In this case the cervix was brought down to the vulva and the posterior lip held with two volcella. A transverse incision in the anterior vaginal vault permitted stripping off the bladder and the peritoneum from the cervix and body of the uterus. The widely-exposed cervix was now mesially divided throughout its length and the superjacent uterus until the hand could be introduced and version and extraction done. The head of the child made extension of this cut for a centimeter and a half. The placenta was manually extracted.

Hemorrhage was checked by packing. The cut in the uterine body and the transverse vaginal opening were sutured with catgut. The preuterine space was drained and the vagina tamponed. The cervix was not sutured. Death occurred on the twenty-third day after delivery of pneumonia. The patient was tuberculous and the pneumonia was of this character. All conditions associated with the eclampsia had vanished before death. Reserving the classic abdominal Caesarean section only for cases of contracted pelvis, Dührssen thinks the vaginal method will fulfil all the desiderata of neatness, rapidity, safety and propriety whenever interference in the interests of the mother or child is necessary. Union of the wound occurs, so as to give very slight scar and not interfere with subsequent normal delivery. The operation is properly entirely extra peritoneal.

Cardiac Syphilis.—W. ZYDLOWICZ (*Klin. therap. Woch.*, Jan. 6, 1901) points out that syphilis shows a certain predilection for the circulatory organs. In many people, especially the aged, there will be found an arhythmic pulse a short time before the appearance of the roseola which in itself is of slight importance, since it disappears with specific treatment, yet it considerably modifies the prognosis. Later, changes in the heart may take the form of an interstitial myocarditis, depending on an obliterating endarteritis or on gummata or on both together. The pericardium, endocardium and the valves are only involved later by continuity. On physical examination, nothing as a rule is found except arhythmia and a moderately enlarged heart, and most cases are put down as neurotic. Yet the correct diagnosis is of great importance, since a cure is easy in the earlier stages, while later sudden death is very apt to follow. The author relates an interesting case in which mercury and iodide of potassium led to a complete cure.

Paroxysmal Hemoglobinuria.—A peculiar condition, in which blood appears in the urine of a patient after an exposure to cold, has been described by many authorities under various names, but, since the blood-cells are not present in the urine, the above name seems the most appropriate. A case is analyzed by W. J. LAMSON (*N. Y. Med. Jour.*, Jan. 19, 1901) in which attacks had occurred for several years, being almost entirely absent during the summer, but coming on very frequently, sometimes daily, during the winter. A typical attack began about 10 a. m., after an exposure to cold, with chilly sensations, cold and cyanotic extremities, increase of the jaundice hue which was constant, and some nausea. He then passed urine of a port-wine color, more frequently and in larger amounts than usual. The chill lasted from one to three hours, and the urine cleared up rapidly as soon as the patient became warm. The pathology of these cases is obscure, no autopsy having been reported. No adequate cause can be found, but it is supposed that, in a patient especially susceptible, a severe chilling disorganizes some of the red blood-cells which pour out their hemoglobin, and this is at once excreted by the kidneys. A change of climate seems to be the only efficacious method of treatment.

Treatment of Fractures.—To determine the value of the Lucas-Championnière method of treating fractures with massage, B. ROSSI (*Klin. therap. Woch.*, Dec. 23, 1900) did some extended experiments on animals which without doubt prove the value of this procedure. Transverse fractures were artificially produced in the middle third of the femur of rabbits; half of these were treated by massage, the other half by immobilization; in the former, firm callus had developed by the eighth day; in the latter, by the fourteenth only. Microscopically, abundant formation of osseous tissue could be demonstrated in the one set, while not a trace of it could be found in the other.

Hemarthrosis of the Knees.—Two peculiar cases of hemorrhage into the knee-joints are reported by R. A. HIBBS (*N. Y. Med. Jour.*, Jan. 19, 1901). The patients were brothers, eleven and fifteen years old, giving the history that two hemophiliac brothers died in infancy. For several years they have had attacks of sudden swelling of the knees, showing definite signs of the presence of fluid. The joints were so painful after such an effusion that walking was difficult for several days. No other joints had been affected and, although at times the attack was accompanied by hemorrhage from the mucous membranes, the latter was not a constant feature.

Leucoplacia.—Despite the fact that leucoplacia has frequently been considered a syphilitic manifestation, J. SELLEI (*Monatshft. f. prakt. Dermatolog.*, Jan., 1901) considers it a separate and distinct disease, for not only can a specific history be rarely obtained, but it is frequently found that the placques become carcinomatous—a condition which is rare in luetic lesions. The latter also do not show such tendency to be limited to the tongue. Certain pathognomonic signs of syphilis are generally absent in true leucoplacia, such as enlarged nodes and rapid disappearance with mercurial treatment and the presence of other syphilides. Pathologically there is found an infiltration in the corium with hypertrophy of the elastic fibers. In many places the lumina of the vessels are much narrowed owing to thickening of the intima.

Suprarenal Extract in Addison's Disease.—The history of an interesting case of morbus Addisonii is related by P. EDEL (*Münch. med. Woch.*, Dec. 25, 1900). When the patient was first seen the disease had lasted six months without remission, while two to three days after the administration of suprarenal extract a marked improvement had already taken place and two weeks later the patient returned to his former laborious occupation. Unfortunately somewhat later, meningeal symptoms developed, the pigmentation reappeared and the patient died after a brief illness. The post mortem showed a tuberculous nodule in one suprarenal, with tuberculosis of the meninges and of the lung.

THERAPEUTIC HINTS.

Catarrhal Jaundice.—As a rule, writes Wm. Osler, the patient can keep on his feet from the outset. Measures should be used to allay gastric catarrh, if present. A dose of calomel may be given and the bowels kept open by salines. The patient should not be violently purged. Bismuth and sodium bicarbonate may be given, and the patient should drink freely of the alkaline mineral waters, of which Vichy is the best. Irrigation of the large bowel with cold water may be practised, but has not given the author good results.—*Practice of Medicine.*

Nasal Douche.

℞ Sodii salicylat.....
Sodii borat..... aa. 24.0 (℥ vj)
Sodii bicarb.....
Sodii chlorid..... aa. 40.0 (℥ x)

M. Sig., grams 4.0 (℥ j) to grams 500.0 (O j) of tepid water.—*Ingals.*

Syphilitic Eruptions.—Startin's lotion is as follows:

℞ Hydarg. chlor. corrosiv. 0.13 (gr. ij)
Ac. nitric dil..... 2.0 (℥ ss)
Ac. hydrocyan. dil..... 2.0 (℥ ss)
Glycerin ..... 4.0 (℥ j)
Aquæ q. s. ad..... 120.0 (℥ iv)

—*Bartholow.*

Acute Rhinitis.—In the beginning an attack may often be aborted, writes E. F. Ingals, by morphine, gram 0.01 (gr. $^1/_6$), with or without atropine, gram 0.0005 (gr. $^1/_{120}$), pulv. ipecac, gram comp. 0.7 (gr. x), pilocarpine hydrochlor., gram 0.008 (gr. ⅛), quinine, gram 0.4-0.7 (gr. vj-x) or a hot sling taken at bedtime. It may also be checked in a similar way by one or two doses of ammon. carbonate, gram 0.7-1.3 (gr. x-xx), ammon. chlorid., gram 1.3-2.0 (gr. xx-xxx), lig. ammon. acetat., tincture of belladonna, tincture of euphrasia officinalis, ammoniated tincture of guaiacum, or an emetic dose of antimony. The action of these is favored by a hot foot-bath containing a handful of mustard. If abortion fails, inhalation through the nose of warm vapors or sprays of ammonium chloride, sodium bicarbonate, or boric acid, are grateful to the patient and aid resolution. Turkish baths, diaphoretics and diuretics may expedite the cure. A useful powder for insufflation is the following:

℞ Cocaina ..... 3 parts.
Sod. bicarb.....
Sod. borat..... aa. 1½
Iodol 25
Magnes. carb. levis..... 1
Sacchar. lactis. ad..... 100 parts.

Spray frequently with cocaine, 1 to 2 per cent. in water or oil. In some cases an aqueous extract of the adrenal glands gives better results. If the disease persists spray with vaseline oil, and give small doses of hyoscyamus or cannabis indica with camphor or phenacetine and quinine. Keep bowels open.—*Diseases of Chest, Throat, and Nasal Cavities.*

Neuralgia.—When this is due to reflex irritation from the female pelvic organs, writes Roberts Bartholow, the preparations of zinc, notably the valerianate, are often extremely beneficial, for example:

℞ Zinci valerianat.....
Ext. gentianæ..... aa. 1.3 (gr. xx)
Ext. nucis vomic..... 0.3 (gr. v)

M. Ft. pil. No. xx. Sig.: One three or four times a day.

Dysentery.—In some cases, writes Andrew Davidson, ipecac, gram 0.7-4.0 (gr. x-℥ j), alone or with opium, is the successful drug. In others ipecac is useless and perchloride of iron tincture, or calomel may succeed. Niemeyer recommends calomel, gram 0.06 (gr. j), and opium, gram 0.015 (gr. ¼), every two hours. Rest is of great importance, and in most instances the diet should be milk, either plain or with lime-water or peptonized. When milk fails, give tablespoonful-doses of beef essence made from a pound of good meat, minced, mixed with water, grams 60.0 (℥ ij), allowed to stand an hour, then placed in a vessel of boiling water for three hours and strained. When prostration is great, wine or brandy is indicated. If the patient be very thirsty whey may be given. Much relief may be obtained from a linseed poultice over the whole abdomen, and, if there is considerable gastric irritation, a sinapism, or spongio-pilene placed in hot water and sprinkled with turpentine, may be applied to epigastrium. If there is fever and sweating a poultice may only increase the suffering. After each stool wash the anus with some disinfecting fluid to prevent excoriation. In giving ipecac, precede by thorough flushing with sodium sulphate or calomel, then administer the ipecac in doses of grams 2.0 (℥ ss) every six, eight, or twelve hours. Vomiting after the first dose will do good rather than harm, but the second dose should be preceded by mustard over the pit of the stomach and tincture of opium, gram 0.7-1.0 (♏ x-xv), internally. If ipecac is inadmissible for any reason, the saline treatment may be resorted to, especially sulphate of sodium, grams 30.0 (℥ j), every morning. Sulphate of magnesium may be helpful. Benzonaphtol, betanaphtol, or resorcin, in large doses may diminish the intestinal fermentation and enemas may be of moderate advantage.—*Allbutt's System of Medicine.*

Chronic Alcoholism.—To relieve the trembling, to diminish the appetite for strong drink, and to relieve the gastric catarrh, the following is very useful:

℞ Zinci oxid..... 4.0 (℥ j)
Piperin ..... 1.3 (gr. xx)

M. Ft. pil. No. xx. One three or four times a day. Small doses of chloral and bromide may be added.—*Bartholow.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

CYTODIAGNOSIS.

WIDAL, the inventor of the agglutination test for the diagnosis of typhoid fever, seems to have added another helpful measure to our diagnostic armamentarium by his work in cytodiagnosis. The effusions that take place into the various serous cavities of the body under pathological conditions show under the microscope a variety in the cell-contents, according to the cause of the effusions. This is especially noticeable in pleuritic effusions, and will probably prove valuable in determining the line of treatment and in making prognoses. For diagnostic purposes, it is only necessary to draw off a few cubic centimeters of serous fluid with an ordinary hypodermic syringe. The liquid is centrifugated after defibrination, and some of the sedimentary part is spread with a platinum loop upon a cover-glass. It is then stained with thionin, or eosin hematein, or with Ehrlich's triacid solution.

Under the microscope the characteristics of the various forms of effusion are revealed. Ordinary pleurisy, for instance, presents in its cellular sediment only small lymphocytes and at times a relatively large number of red blood-cells. The lymphocytes show a marked tendency to run together. It will be remembered that this form of pleurisy has of late years been considered to be tuberculous in origin. Even when tubercle bacilli cannot be found in the sediment, the injection of the pleuritic exudate into animals often results in the development of tuberculosis, and it is well known that tuberculosis may subsequently develop in patients who have suffered from so-called idiopathic pleurisy.

Pleuritic effusions in distinctly tuberculous patients present quite a different cell-formula from that of what may be called latent tuberculous pleurisy. Very few cells are found in the centrifugate, rare lymphocytes and scattered red blood-cells. The characteristic find is a certain number of old, deformed polynuclear leucocytes, the nuclei of which are very irregular and contain deteriorated neutrophile granules. This same cell-formula occurs in the exudate of tuberculous hydropneumothorax, and it is strangely suggestive of the chronicity of the pathological process at work.

Mechanical hydrothorax, occurring in cardiac and renal cases, or because of compression, presents a cell-formula characterized by the number of large endothelial cells. These have fallen from the surface of the pleura, and often retain their connection with each other by twos or threes. If the effusion is old, the cells are more apt to occur singly, their adhesions having given way during their maceration in the fluid of the exudate.

Pneumococcus pleuritic exudate presents, according to Widal, the most striking picture of vital reaction and defense against the invading infectious agent. A few lymphocytes and red blood corpuscles are found, but most of the cells are polynuclear leucocytes of very active vitality as regards their phagocytic properties. There occurs in addition a certain number of large mononuclear lymphocytes, evidently of endothelial origin, but very seldom found adherent to one another. These are, in Widal's words, veritable macrophagocytes, and are often found to have engulfed polynuclear leucocytes.

Streptococcus pleurisy gives an exudate without the characteristic signs of reaction, or, at most, only evidence of an abortive effort to throw off the infection. The cell-formula consists mainly of polynuclear neutrophiles with deformed nuclei. Exudates that occur during the course of typhoid often present a number of large mononuclear leucocytes significant of successful reaction to the infection.

Serous effusions into other cavities present cell-formulæ that bear analogies to those of pleuritic exudates. Although Widal was not able to culti-

vate any form of germ from the articular exudate of 15 cases of rheumatism, the character of the cells present, mostly polynuclear leucocytes of active type, showed a very marked reaction to infective invasion. Traumatic arthritis presents a distinct analogy to mechanical pleurisy, characterized by the presence of cells from the serous lining of the joints. The arthritic effusion into tabetic joints has the general character of a traumatic arthritis. Most cases of hydrocele, according to their cell-formula, are also of mechanical origin.

ACUTE DILATATION OF THE HEART AND SUDDEN DEATH.

THE fact that death occurs quite unexpectedly in children who are suffering from diphtheria, or even in those who have apparently recovered from an attack, makes the subject of heart dilatation a matter of great importance in the treatment of this disease, as well as in certain cases of influenza and rheumatic fever in which it sometimes causes fatal syncope.

It has been thought by some that sudden death after diphtheria is caused by a neuritis of the vagus; but, from a careful pathological study of the heart by several observers, it has been shown that the fatal syncope that follows diphtheria is probably due to a diseased condition of the heart itself rather than to disease of its nervous mechanism. In some cases of death following diphtheria, a fatty degeneration of the cardiac muscle has been found, and in other similar cases, as well as in sudden death following rheumatic fever, very marked degeneration of many of the cardiac muscular fibers, and complete destruction of some parts of them have been observed.

Such investigations naturally lead us to conclude that there must be more or less degeneration in a large proportion of the cases that recover, and the practical question arises, whether such cardiac degeneration may be detected by clinical investigation.

This has been answered and well discussed by Dr. W. B. Lees (*British Medical Journal*, January 5, 1901), in an article entitled "Acute Dilatation of the Heart in Diphtheria, Influenza, and Rheumatic Fever." He says that from his experience with such cases, the clinical indications which should be sought for are: Feebleness of the pulse-wave; feebleness and diffusion of the cardiac impulse; extension of the cardiac dulness to the left; feebleness of the first sound at the apex, with accentuation of the pulmonary second sound and a marked accentuation of the aortic second sound. He has found that in children suffering from diphtheria the cardiac dulness is usually increased toward the left. If this extends two fingerbreadths to the left of the nipple line, there is urgent peril and the child must not be allowed to sit up in bed under any consideration. A rapid increase in dulness sometimes takes place in a few hours, and is frequently accompanied by vomiting, which is a sign, and an unfavorable one, of acute cardiac dilatation. Unless careful percussion and palpation is continued during apparent recovery from such an attack the patient may be in danger at any time from exertion. In time, however, with extreme care, the heart will usually return to the normal size.

In influenza, rapid dilatation of the heart frequently occurs within a day or two after the onset of the disease, and it sometimes causes fatal syncope. Here, as in diphtheria, two fingerbreadths of dulness indicate danger. In *Jacobi's Festschrift*, Forscheimer called attention to this condition and has described with striking clearness two types of the disease. He is inclined to lay great weight on the action of the toxins of the influenza bacillus on the medullary center.

In rheumatic fever, even in slight attacks, acute dilatation of the heart seems to be invariably present, but, although so much more frequent than in diphtheria or influenza, it is not nearly so fatal, probably because the several toxins affect the cardiac muscle differently. When, however, dulness is found in a patient with rheumatism, which extends beyond two fingerbreadths to the left of the nipple, and is accompanied by sudden vomiting, pallor and coldness, there is great danger of collapse.

It is very evident from these well-recognized facts that greater attention to the study of cardiac dulness will avert disastrous results and that fewer cases of sudden death will have to be reported if sufficient caution is taken.

THE PRESENT STATUS OF RHEUMATIC FEVER.

THE gradual drift of medical opinion is not more strikingly shown with reference to any disease than in the case of rheumatic fever. Many and persistent have been the theories regarding its etiology, from the earlier views of Cullen in 1784, who taught that the disease was due to the direct

influence of cold upon the joints, to the *fin de siècle* hypotheses of neurochemical action.

In the current number of the *Practitioner,* January, 1901, there is presented a review of the present status of rheumatic fever of more than usual interest. Papers by Drs. Newsholme, Poynton, St. Clair Thomson, Gibson, Still and Luff on the Epidemiology, Pathology, Rheumatism and the Throat, Effects of Rheumatism on the Heart, Rheumatism in Childhood and the Treatment of Rheumatism, respectively, afford a survey well calculated to impress the reader.

In his discussion of the Epidemiology of Rheumatic Fever, Dr. Newsholme dissipates some popular misconceptions regarding this disease. He insists that rheumatic pains, so called, those usually induced by the influences of wet weather, have absolutely no connection with rheumatic fever, and that this disease has been shown, by statistics drawn from wide sources, to be much more prevalent in dry seasons than in wet ones. The conclusion is expressed that a heavy annual rainfall is usually associated with a low amount of rheumatic fever and a small rainfall with an excessive amount of rheumatic fever, though no exact proportion of the two factors can be predicated.

He further shows that the incidence of this affection is sufficient to warrant the belief in the epidemic character of the disease. Two kinds of epidemics are to be distinguished, the explosive and the protracted. The explosive epidemics terminate in one or, at the most, in three years The protracted epidemics are seen chiefly in large centers of population or when the statistics of a large country are being studied. The author believes in the contagion theory and hazards the surmise that inoculation of the contagion of rheumatic fever may be caused by domestic vermin.

Dr. Poynton presents the various theories which have arisen to explain the pathological features of the disease, and finds favor with the infectious theory. The diplococcus, isolated by himself and Paine (*Lancet,* September 22, 29, 1900) from twelve cases of rheumatic fever and demonstrated in the pericardium, the pleura and cardiac valves, is held to be *a* cause of rheumatic fever, and he moreover says that one of the most important sites of infection is the throat, in which connection, the paper by Ullman in this week's issue of the Medical News is of interest. The paper following, by Dr. St. Clair Thomson, on Rheumatic Fever in Relation to the Throat, discusses this same question very clearly. He considers the two points of view so frequently debated, that, on the one hand, the poison enters the body through the tonsil, the inflammation of which may be the earliest indication of the systemic affection, or that certain inflammations of the tonsils occur with greater frequency in patients with an arthritic diathesis. Each of these views is worthy of some consideration, and although our knowledge is not, at the present time, enough to fully answer the query, a fuller insight into the precise character of the anginas will probably answer these questions. At all events, it seems certain that from thirty to eighty per cent. of all cases of rheumatic fever are associated with tonsillar angina and that no direct relationship seems to exist between peritonsillar angina (quinsy) and rheumatism.

It is generally admitted that heart lesions may precede the articular symptoms and Dr. Gibson, in his paper, brings out the significant fact that it is unnecessary to consider the heart lesions as complications of the articular changes any more than it is to discuss the reverse position. The two are the same disease, similar in kind, if not in degree, and the query arises, not, how shall the cardiac complications be avoided, but how shall the cardiac rheumatism be treated. He enjoins absolute rest, a milk diet, the salicyl series of compounds, the iodide of sodium, as an absorbent and counterirritation, by means of small fly blisters, applied every night or every other night, over the precordia.

To measure the frequency of rheumatism in childhood by the number of patients who come for treatment of the articular lesions is entirely to misunderstand the prevalence of this disease in early life, says Dr. Still in his paper. The heart implication may occur alone as the earliest symptom and no more significant feature is brought out in the discussion than the importance of the early recognition of rheumatism in childhood. Slight symptoms are apt to be overlooked and early manifestations of pain are only too liable to be dismissed as "growing pains." As Dr. Still points out, "it is by paying attention to the 'day of small things,' the apparently trivial aches and pains, and the various associations which make up the picture of rheumatism in childhood, that we may hope, in some cases at least, to prevent those terrible results which are too often seen from neglected rheumatism in children."

Dr. Arthur P. Luff, in discussing the "Treatment," lays stress on the employment of salicin and the salicylates originally introduced by Maclagan and the German school in 1874, and now so widely used the world over.

ECHOES AND NEWS.

NEW YORK.

Mount Sinai Appointments.—Dr. Hiram N. Vineberg has been appointed adjunct attending gynecologist to the Mount Sinai Hospital.

Dr. Moore Reinstated.—The official reinstatement of Dr. J. W. Moore of Bellevue Hospital took place last week. He resumed his duties in the medical wards by order of Commissioner Keller.

Red Cross Hospital.—William T. Wardwell, President of the Red Cross Hospital in West Eighty-second Street, has given $40,000 to aid in the erection of a new hospital much needed by the management.

For Pure Food.—Another bill carrying out a recommendation of the Governor, and introduced by Senator Ambler, transfers to the State Agricultural Department the supervision of all food products, except beverages, confectionery and drugs. The bill also prohibits the sale of adulterated food in this State and defines what foods shall be judged adulterated.

Charity Societies Protest.—Governor Odell's idea for a new State Board of Charities, which was embodied in the bill introduced in the Legislature recently, does not meet with the approval of the charitable societies of New York. The bill calls for the abolition of the present board and substitutes for it a commission of three members, consisting of a commissioner and two associates.

Omega Upsilon Phi Fraternity.—The Omega Upsilon Phi Fraternity (medical) has just organized two new chapters, one at the University of Colorado, composed of fifteen students and several members of the faculty; the other a "graduate chapter" in New York City, to be known as the "Henry C. Coe Chapter," in honor of Professor Coe of the University and Bellevue Hospital Medical College.

State Board of Health Legislation.—The last of Governor Odell's State Commission Consolidation bills was introduced in each branch of the Legislature January 21st, when a bill abolishing the present State Board of Health and providing for a single-headed commission was introduced by Senator Audett. The Commissioner of Health is to be appointed by the Governor, and is to be a physician of ten years' experience in actual practice of his profession. The term of the first Commissioner is to expire on December 31, 1904, and thereafter his successor shall be appointed for a term of four years. The Governor is to appoint the Commissioner within twenty days after the act takes effect, when the terms of the present members of the State Board of Health and the Secretary of the Board shall expire. The Commissioner is to receive a salary of $3,500 and is empowered to employ such clerical assistance as may be necessary. A State Bureau of Vital Statistics is created, to be under the Commissioner's supervision. The powers and duties of the present board are to devolve upon the single-headed commission.

Typhoid at Sing Sing.—The prevalence of typhoid fever among the prisoners of Sing Sing has brought the attention of the State Board of Health to the institution and it looks as though that body would condemn the prison for its unsanitary arrangements and recommend that a new prison be built. On Saturday Charles F. Wingate, consulting engineer to the State Board of Health, made an examination of the prison's sewerage system. He found that the prison cells were but four feet above tidewater and that the sewage emptied into the Hudson at low tide backs up under the prison buildings. He also condemned the whole plumbing system. There are forty cases of typhoid among the convicts, and there have been two deaths from the disease in the past two months. The cases were first attributed to the impure condition of the Croton water with which the prison is supplied. Dr. Daniel Lewis of New York, President of the State Board of Health, believes the prison should be moved to higher ground. The State owns several hundred acres of high land east of the prison which would make a suitable site. It is the general impression, however, that if a new prison is to be built it will be in another part of the State. The prison was built in 1834.

PHILADELPHIA.

University of Pennsylvania.—Dr. J. Whitridge Williams of Johns Hopkins University addressed the Barton Cooke Hirst Obstetrical Society, January 16th.

Dr. H. A. Kelly.—Dr. Howard A. Kelly of Baltimore addressed the Student Volunteers of this city on the study of the Bible, Saturday evening, January 19th.

Norristown Hospital.—Dr. Mary M. Wolfe has been elected chief resident physician in the female department of the State Hospital for the Insane at Norristown to succeed Dr. Susan J. Taber, Dr. Alice Bennet withdrawing her name as a candidate after several tie ballots had been taken.

Cost of Maintaining Insane.—The Secretary of the State Board of Charities gives the following as the weekly cost of maintaining each patient in the various hospitals for the insane in Pennsylvania: Harrisburg, $3.75; Danville, $3.73; Norristown, $3.20; Warren, $3.50; Dixmont, $3.85; Wernersville, $2.96.

Filtration Expert Deposed.—The expert bacteriologist in charge of the test filtration plants of the city has been relieved because of errors in his work and computations. Supposed sterile jars were contaminated, one result of this being the statement that Schuylkill water contained 480,000 germs per cubic centimeter, which was reduced to 40 or 50 by filtration. It was also claimed that a percentage of 99.87 had been reached by the filtration methods under use.

The tests will be continued under new supervision.

Pharmacists to Suggest New Laws.—The Pennsylvania Pharmaceutical Association will recommend some changes in the law as a result of the recent numerous prosecutions by the Board of Examiners. One feature is that druggists will be divided into two classes, first, those who sell prepared articles in the original packages, and, second, prescription druggists. Another feature is that the Commonwealth provide the expenses of examinations, enforcements of the law, etc., instead of having the Board of Examiners do this and keep the fees and fines as their compensation.

College of Physicians.—The Section on Gynecology met January 17th. Dr. E. E. Montgomery read a paper on the "Treatment of Prolapsus Uteri." This depends on the degree, repair of the perineum with resection of a portion of the anterior vaginal wall sufficing in some cases. In others ventral suspension should be added with possibly shortening of the uterosacral ligaments as well. Accompanying hernia should be treated by uniting the folds of peritoneum to obliterate Douglas' cul-de-sac. An extreme degree of prolapse of a large uterus demands hysterectomy. This should be done through the anterior vaginal fornix, seizing the broad ligaments with the angiotribe and applying chromicized catgut ligatures in the grooves thus made. Dr. Charles P. Noble reported a case of cancer of the cervix and pelvis following supravaginal hysterectomy. This is the only case in his experience, which includes 175 hysterectomies for fibroids and a larger number for other conditions. There was reason for believing that an unrecognized cancer existed at the time of operation. Dr. George E. Shoemaker reported a case of salpingitis with obscure localizing symptoms. Pain was felt in the epigastric and gall-bladder regions, the point of greatest tenderness varying from the epigastrium to McBurney's point. Diagnosis was made by examination under ether. Operation showed the tip of the appendix adherent to the right ovary, but the appendix appeared otherwise normal.

CHICAGO.

Applicants to Practise Medicine.—It is said that about 75 applicants for certificates to practise medicine or midwifery in Illinois were examined by the State Board of Health at its meeting, recently held in this city.

Governor Yates' Message.—The Governor recommends the enactment of a law making boards of county commissioners boards of health in their respective counties. He also recommends legislation for the establishment of a sanitarium for the treatment of tuberculosis.

Anti-Spitting Ordinance.—Such an ordinance was passed by the City Council January 14th. In brief, it is as follows: *Whereas*, Spitting on sidewalks, in public places and in public conveyances is detrimental to health, by reason of the danger of spreading contagious disease, and is also a public nuisance which should be abated; therefore, be it *Ordained by the City Council of the City of Chicago* that no person shall spit on any public sidewalk or on the floor of any public conveyance, or on the floors of any theater, hall, assembly room or public building; that any person violating the provisions of this ordinance shall on conviction be fined in a sum of not less than $1.00, nor more than $5.00; that this ordinance shall be in effect after its passage and approval by the Mayor.

Observations of the Blood in Anemia.—At a joint meeting of the Chicago Medical Society and the Chicago Society for Internal Medicine, held January 16th, Dr. Joseph A. Capps presented a preliminary report on this subject. A study of fourteen cases of chlorosis showed that the red corpuscles in all cases have a smaller average diameter than in normal blood. The color index is constantly very low, while the volume index is decreased to a less degree. The red cells in twenty-four cases of secondary anemia are also subnormal in diameters. The color index is not so low as in chlorosis. The volume index falls also, but never so much as the color. The size of the corpuscles in seventeen cases of leucemia and the relation of hemoglobin to volume are essentially the same as in secondary anemia. Thirty-one cases of pernicious anemia give a decided increase in the average diameter of the cells. The color index is high, and the volume index still higher.

Home for Consumptives.—Efforts will be made by the Illinois Society for the Prevention of Consumption to induce the Legislature to appropriate $200,000 for the establishment of a State sanitarium for the care and cure of cases of that character. Plans and estimates for the building of the sanitarium, which have been under way for over a year, have been completed and Dr. John A. Robison, Secretary of the Society, has been instructed to submit them for the approval of the State Board of Health. The project is endorsed by Mayor Harrison, Health Commissioner Reynolds, and the Illinois State Medical Society. Preliminary to the introduction of the plan in the Legislature, the Society expects soon to stir up agitation by the free distribution of literature, showing the necessity for the isolation of hopeless consumptives and the need of extending aid to the afflicted who are unable to care for themselves. As the purpose of the sanitarium primarily is to give free aid, the Legislature also will be asked to provide for a yearly appropriation to maintain the institution.

Chlorosis, Its Diagnosis and Treatment.—A paper on this subject was presented by Dr. Gustav Fütterer. From his clinical experience and experimental observations, he emphasized the following points: (1) Great attention should be given to the study of chlorosis clinically; clinical observation should be controlled by taking the specific gravity of the blood; a very energetic treatment, mainly with beef-juice, properly pre-

pared, should be instituted at once and continued until the specific gravity of the blood has become normal. (2) Chlorosis or secondary anemia in tuberculosis must receive the same consideration and treatment, no matter what other treatment may be employed. (3) It is advisable to cause an artificial anemia in animals to be inoculated with suspected tuberculous sputum for diagnostic purposes, as a finer reaction will take place, and more accurate and probably quicker results can be expected. (4) Chlorosis in early years, or secondary anemia in later years, permits a round ulcer of the stomach to form and prevents its healing, while the presence of a normal percentage of hemoglobin brings about prompt repair, and that, therefore, chlorosis or secondary anemia, coexisting with round ulcer of the stomach, should receive first attention, before any so-called ulcer treatment is begun. (5) Therapeutic measures, particularly fresh and properly-prepared beef-juice, enable physicians to bring about a normal composition of the blood, both in chlorosis and in secondary anemia, as a rule, in a very short time.

Ureteral Implantation Into the Bowel.—Dr. Jacob Frank read a paper on this subject before the January meeting of the Chicago Academy of Medicine. After detailing considerable experimental work on ureteral implantation into the bowel, the essayist reaches the following conclusions: (1) The technic is all that can be desired; (2) bilateral implantation into the rectum simultaneously is primarily and remotely an extremely dangerous procedure, and can have no favorite place in human surgery; (3) While no single permanent implantation of the ureter into the rectum has demonstrated an absence of inflammatory reaction on the part of the kidney, nevertheless the essayist is of the opinion that it must be regarded as justifiable where other means fail, and has a limited place in pelvic surgery; (4) while stricture has not taken place, it cannot be said with confidence that scar contraction at the opening into the rectum will not in months or years produce one; (5) that the rectum will tolerate the presence of urine cannot be doubted, and has been proven to do so by many experimenters. In order to overcome the difficulties of stricture and ascending infection, Tuffier and Maydl, each claiming priority, proposed and carried out the implantation of the ureter by preserving the valve-like folds of cystic mucous membrane at the mouths of the ureters, thus protecting the kidney against infection. As long as the ureter is permeable and its sphincter functionating, so long is the kidney protected. This fact was proven to the speaker's satisfaction in his experimental work on vesico-rectal anastomosis.

GENERAL.

Plague Still Feared.—In spite of the reports that the postmortem examination of the remains of the three members of the crew of the British steamer "Friary" at Hull did not reveal that they were stricken with the plague, the authorities have ordered the "Friary" not to dock, but to anchor in the Humber. Two more deaths among her crew have occurred with symptoms of the plague. Five of the crew are isolated.

St. Louis Medical Society of Missouri.—At the meeting of January 19th, 1901, Dr. William Bayard Shields read a paper on "Influenza, More Especially its Effects on the Respiratory Organs and Accessory Nasal Sinuses." The following resolution was introduced at the meeting of January 5th, 1901: "*Resolved*, That two hundred and fifty dollars ($250) of the funds of this Society be set aside for the purposes of the special committee on State Legislation of the Medical Association of Missouri."

Medical Legislation in Germany.—Professor Neisser, of the University of Breslau, has just been severely censured and fined for having published an account of certain experiments to which he had subjected children who were patients in the University hospital. In obvious connection with this case is an order which has just been promulgated by the Prussian Minister of Public Instruction, directing the attention of those who have the management of clinical and polyclinical hospitals and similar institutions to the fact that medical operations for any purposes save those of the diagnosis, cure and prevention of disease are forbidden, even when otherwise permissible from the legal and moral point of view, in the case of minors, in cases in which express premission has not been given, and in cases in which this permission has not been preceded by a proper statement of the injurious consequences which might possibly result from the operation.

Obituary.—Dr. Charles Wesley Purdy recently died at Chicago of a complication of diseases, caused by overwork. He was born in Kingston, Ontario, in 1846, and was graduated from the Queen's University with high honors. Dr. Purdy made a life study of diseases of the kidneys, and wrote several books on the subject. He received several degrees from the Royal College of Physicians and Surgeons of Canada.

Rev. Charles E. Conrad, M.D., died last week at Quincy, Ill., aged eighty-one years. He was born in Siberia, and educated for the church and medicine at Berlin; went to British India in 1848, and, as the missionary who could heal, was sought after by thousands of the natives. He established asylums for lepers and epileptics at Lohordagga; was in Calcutta during the Sepoy outbreak, and in 1853 came to America, settling in Quincy. He established four flourishing Evangelical churches in that section and retired about three years ago.

Dr. Benjamin Brown, of Chicago, died January 17th, after a year's illness, aged sixty-six years. He was prominent both as a physician and in Republican politics in Chicago.

Omaha Afraid of Small-Pox.—Thirty-two hundred children in the Omaha public schools must either bare their arms to the vaccine point or discontinue their school attendance. Nine cases of small-pox have been reported this month. Ten last month.

CORRESPONDENCE.

A CORRECTION.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I beg leave to amend the item in "Echoes and News," page 64, January 12th, 1901, under the caption "Death from Strychnine." The inmate of the Montefiore Home, a locomotor ataxic, died on Saturday, the 5th inst., after the administration of the dose $^1/_{30}$ of a grain, not *gram*, as stated in the source from which your note was taken. The order was given to administer $^1/_{30}$ of a grain of strychnine with antipyrin and acetanilid —a dose which he had taken on previous occasions. He died the same afternoon.

EDWARD S. PECK, M.D.,
President of the Medical Board of the Montefiore Home.

New York, January 15, 1901.

OUR LONDON LETTER.

[From Our London Correspondent.]

LONDON, January 1, 1900.

THE VITAL STATISTICS OF LONDON—A DIMINISHING BIRTH-RATE—THE DANGERS OF "GEYSERS" IN SMALL UNVENTILATED BATH ROOMS—FATAL ACCIDENT—THE ANNUAL REPORT OF THE SANITARY COMMISSIONER FOR THE PRESIDENCY OF BOMBAY FOR 1899—96,000 DEATHS FROM PLAGUE—THE DANGERS OF CELLULOID COMBS—SEVERE CASE OF BURNING.

THE report of the Medical Officer of Health for London has just been issued. It deals with 1899, for the compilation and collation of the statistics occupy the officials nearly a twelvemonth. The variations in the rates of marriages, births and deaths for the last half century are shown in a very striking manner by means of diagrams. Speaking generally, the rates of births, marriages and deaths have been lower in the second half of that period than in the first. Up to 1877 the marriage rate was 18.9 per 1000; since then it has been constantly lower, reaching the lowest level in 1887 and 1888, rising sharply in 1896 and 1897, and almost attaining th previous mean in 1898, but falling back last year to 18.4. The number of children born in 1899 was 133,585, giving a birth rate of 29.3, the lowest on record. Up to 1885 the mean was 35.5. The statistics of England and Wales show a similar diminution of the birth rate. In 1899 the deaths in London were 87,819, giving a rate of 19.3 which is below the average, 22.6.

A fatal case showing the dangers of using geysers in small unventilated bathrooms has occurred. A boy, aged fifteen, took a bath under these conditions. Some time afterwards a noise was heard, and the door was therefore broken open. The boy was found lying on the floor insensible. Medical aid was summoned but death took place in the afternoon. When the door was opened, the water in the bath was still warm, but the geyser was turned off. The only possible ventilation was by the window which was closed. The geyser had been in use 2½ years and was frequently cleaned. There was no smell in the room. Another person had taken a bath that morning and the geyser had worked perfectly well. The doctor who was called found the boy comatose. Oxygen was administered without avail. Death was due to carbonic oxide poisoning. The room was too small for a bathroom, measuring 8 x 8 x 4 feet. An expert called at the inquest testified that the flame was an ordinary gas jet and that the geyser worked perfectly well. The fatal result was evidently entirely due to the small size and non-ventilation of the room.

The annual report of the Sanitary Commissioner for the Government of Bombay for 1899 has a novel and melancholy interest. Its brightest feature is the reduced death rate of the European civil population, which was 12.52 per mille, against 13.14 in the previous year. Of the 231 European deaths in the Presidency, 16 were from plague and 12 of these occurred in the city of Bombay. The European birth rate was low—11.96 per mille. Eurasians on the other hand showed a rise in mortality, their death rate being 21.72, as against 19.84; in 1898 the birth rate was 19.49. In the native population there was a great increase of both births and deaths, as compared with the previous year. Violent variations in these rates have been frequent in Western India since the introduction of the plague. Thus in 1895 the births and deaths in the Presidency were 674,000, and 538,000; in 1896, 691,000 and 596,000; in 1897, 629,000 and 749,000; in 1898, 582,000 and 548,000; in 1899, 685,000 and 672,000. The birth rate of the native population was 36.42 in 1899, as against 30.94 in 1898; the death rates in these periods were 35.7 and 29.16. Terrible mortality returns are recorded in the urban population, thus at Nosch the death rate was 153, in Poona 128, at Karad 99, and at Harachi 95. The death rate of Bombay city was much lower than these figures—69. Ninety-six thousand people died of plague in the Presidency in 1899, the largest number yet recorded. Cholera claimed 8579 victims, twice as many as in the previous year, but far fewer than in many years of the last two decades. The small-pox statistics are eminently satisfactory and are a testimony of the value of the vaccination work done in the Presidency. There were only 1946 cases of small-pox, the lowest with two exceptions in the past 12 years. The deaths from fever were 228,000, which was below the decennial mean number. The mortality from dysentery and diarrhea was 74,736, a rather alarming increase; 2772 people died from drowning and 1444 from snake bite.

The dangers of celluloid combs is forcibly illustrated by a case which has recently occurred. A lady was sitting before a drawing-room fire, when the comb in her head became ignited. The flames were extinguished with difficulty and not before she was severely burned. She is progressing favorably but is not fit to be moved. Celluloid, which is a mixture of gun-cotton and camphor, is inflammable at a low temperature and therefore extremely dangerous. Several serious accidents have previously occurred from its use—one from the ignition of a celluloid collar.

EMPHYSEMATOUS GANGRENE—NON-MALIGNANT CANCER—ENDOTHELIOMA OF THE BREAST—CYSTIC ADENOMA OF THE SUPRARENAL BODIES—SARCOMA OF THE STOMACH—MALARIA—PROTECTION FROM MOSQUITOES IN MALARIOUS DISTRICTS—RETROFLEXION OF THE GRAVID UTERUS—IMPERFORATE ANUS—ANGIOMA SCROTI—NON-RHEUMATIC NODULES.

E. M. Corner and H. D. Singer contributed a paper on the bacteriology of acute emphysematous gangrene at the Pathological Society of London, December 4, 1900, stating that it must be differentiated from hospital gangrene and the gangrene due to injuries to the vessels, and emphasizing two points, (1) the established identity of the bacillus aerogenes capsulatus and the bacillus emphysematosus, (2) the clinical distinction between cases due to mixed aerobic infection and cases due to mixed anaerobic infection. Under either of these classes both typical and atypical cases are found. Such varieties appear to be due to the differences in the virulence of the infecting germs, which had been experimentally proved to vary between non-pathogenic and highly deadly organisms. The prognosis in the cases of mixed anaerobic inoculations is better, as a rule, than in those of associated aerobic infections, probably because in the former much more gas is generated. This means an earlier diagnosis and a prompter treatment. The management of these patients depends upon the diagnosis. If this be early free incisions and continuous antiseptic bath are enough, if late or this plan fails amputation wide of the zone of infection must be promptly done. The variations in the treatment as recommended by many authorities probably are due to wide range of differences in the noxiousness of the bacilli. There are cases in which amputation was done through the infected tissues, which always presented recurrences. Hence, only healthy tissue should be included in the flaps. Three kinds of bacilli are recognized, of which the bacillus aerogenes capsulatus is the most common.

S. Bontor described a case of non-malignant cancer of the left breast in a female who died at the age of seventy-seven years of asthenia, after having suffered the growth for twenty-three years, without ulceration, pain, secondary deposits in any of the lymphatic glands or internal viscera, with, however, similar or secondary growths in the opposite breast and in the skin of the abdomen. When the patient was fifty-four years old the growth appeared as a hard lump in the breast and the skin became scaly. There are other such cases recorded in literature. This was confirmed as cancer by a macroscopical and microscopical examination.

A. G. R. Foulerton exhibited macroscopic and microscopic specimens from a case of endothelioma of the breast and glands of the axilla removed from a woman, fifty-six years old, who had had the neoplasm three years. All the specimens were of uniform deep red color. The microscopical appearances were of rows of cells supported by fibrous trabeculæ and forming the walls of blood-vessels from which extravasation had in many instances taken place. He considered that as advantageously distinct from the carcinomata and sarcomata should be classified the endotheliomata which arise from the small and large lymph-spaces of the body, namely, blood-vessels, lymph-channels and nodes, pleura, pericardium, peritoneum, etc.

H. Thursfield showed a stomach removed from a four-year-old child the seat of a primary diffuse sarcoma. Growths later than that in the stomach had appeared in the jaw and thyroid gland. At the necropsy examination of these was denied. The stomach-wall was diffusely and greatly thickened and its cavity enormously dilated. It was a small round-celled sarcoma. Statistics show that primary sarcoma of the stomach is very rare and even secondary sarcoma is not common. When present its form is discretely nodular, rather than uniformly diffuse. Four cases are mentioned in the annals of the society and there is one specimen very like the author's in the museum of the Royal College of Surgeons in England. This case, however, is unique in its occurrence in a really young child.

P. Manson, at the Royal Medical and Chirurgical Society, December 11th, communicated a brief résumé of the parasitology of malaria. In 1896 and 1897, when this subject was widely discussed, it was known through what cycle the organism passes within the human body, but it was known definitely through what cycle it passes without the human blood. Since the disease is essentially one of the blood, and since it is specifically epidemiologically and geographically distributed the mosquito was looked upon as a very probable host for the organism. After two or three years of labor Ross demonstrated conclusively the truth of this theory. He first established the endogenous and exogenous phases of the coccidium Schübergii in bird malaria and then the strict analogy to it of the hemomenas præcox, the parasite of estivo-autumnal fever. This organism in man has an asexual existence, attacking the red cells, developing, being liberated and in the new generation attacking other red cells. In the mosquito, however, it has a bisexual life. The place of the malarial parasite in zoölogy is difficult as yet to fix, many of its forms have several names and some have none. Under recent observations the cimeria is the endogenous phase of the coccidium. Two things are necessary to complete our knowledge of the life-history of these organisms, first, what circumstances determine the distinction of the merozoites and whether they proceed to the mosquito phase (bisexual cycle) or to the human phase (Golgi cycle); and, second, what becomes of the parasite during the long interval which sometimes elapses between the infection and the appearance of the attack. It is also desirable to know why crescents are so common in England and in the late autumn in Italy and not in tropical Africa and in the summer and early autumn in Italy. Among the mosquitoes only the *Anopheles* had been identified with infection, of these forty-eight species are known. The organism has been found in *Anopheles funestus, costalis, claviger, pseudopictus,*

superpictus, bifurcatus, and the as yet unidentified species of Ross. None of the two hundred and fifty classified species of *Culex* has been found an efficient carrier of the malarial parasite, but very few have been tested, namely, *Culex mimeticus, pipiens, teniatus, nemorosus, malariae* and three unidentified species of *Culex* experimented with by Daniels in British Central Africa. Recent observations of the natives in malarious districts show that seventy or eighty per cent. of children under one year contract the disease. Thereafter until the tenth or twelfth year the number diseased gradually declines, when a kind of immunity to the disease is established. Among postmorten examinations it is found in these regions that practically all deaths of malaria occur in children. Malarial pigment was present in twenty-five per cent. of all cases over one and under twelve months of age, in none under one month old, in fifty-four per cent. of those over one and below two years, in eighty-one per cent. of those between two and five years, in eighteen per cent. of adults above thirty years of age and in steadily decreasing ratios with each ascending decade thereafter, out of twelve hundred and eighty-nine cases examined for it by Daniels. Prophylaxis against malaria included four points, to avoid the natives, to take quinine, to destroy mosquitoes and to protect from mosquitoes. Absolute protection is an impossibility, but relative protection is both possible and of immense value.

L. SAMBON and D. C. LOW reported their experiments during the expedition in behalf of the Colonial Office and the London School of Tropical Medicine in the Campagna and in London. The idea of a relation between the mosquito and malaria existed even among the ancients and is found to-day among the tribes of malarial East Africa, where the same word means the fever and the gnat. Twenty years ago Manson proved that the mosquito is the host of the filaria Bancroïti and later Smith and Kilbourne that the pirosoma bigeminum is transmitted among cattle by the common tick. The experiments carried out by the authors were planned by Manson and consisted in the following parts: First, mosquitoes were bred, reared and infected in the Campagna and after several failures were finally successfully shipped to London. Here two healthy individuals allowed themselves to be bitten by insects of different shipments and each developed typical benign forms of malaria. The second feature of the observation was carried out in Italy by the speakers. In a special cottage designed to have the windows and doors open at all times, but carefully closed against the insects by fine netting, the observers lived throughout the malarial season, July 15th to October 15th. They took care not to go out earlier than an hour after sunrise or later than an hour after sunset, and at first wore veils when they were out-of-doors. This protection was finally dispensed with and the danger of being bitten was found to be infinitesimal. The conclusions they felt absolutely established are that only the mosquito is capable of transmitting the malarial organism, that protection from its bite means immunity, that such protection is easily obtained and that its maintenance does not interfere at all with the ordinary avocations of life.

W. J. SINCLAIR, at the Obstetrical Society of London, December 5th, contributed observations on the diagnosis and treatment of retroflexion of the pregnant uterus. The symptoms give an almost unmistakable syndroma and the treatment in a series of fifteen recent cases he had found to be simply the introduction of a watch-spring pessary after emptying both the bladder and the rectum. If the patient lie upon the side or as nearly as possible on the stomach, in a few hours a reposition will occur. In one patient the womb was held down by a fibroid tumor on its posterior wall, and in the cul-de-sac of Douglas. Abortion may be caused by a uterus so imprisoned. Abdominal section for a gravid uterus retroflexed is to be deprecated, but after an abortion ventral fixation is much recommended.

ALBAN DORAN in the discussion agreed that irritability of the bladder and retention of the urine are important diagnostic signs. Among recently reported instructive cases he names that of Konrad (Budapest) where relief came too late. Sloughing of the vesical mucosa and death three days after reduction occurred. Also Unterberger where pressure on the urethra had distended the bladder and finally the urachus. Also to Gemmell's (Liverpool) patient where abdominal pain and retention of urine led to the diagnosis of retroflexed gravid uterus. A fibroid was found to be the cause, was enucleated by abdominal section and the pregnancy continued to term. Szants reported a case where the relaxation due to typhoid fever was at the bottom of the malposition, manually reduced, and of its subsequent recurrence also treated in the same way.

J. I. PARSONS has found the air-ball pessary very serviceable and any slow method better than immediate reposition by hand. Adhesions in this malposition are very common, but he had never found such a uterus pregnant. If he ever did, abdominal section, liberation and ventral fixation would be the treatment.

A. L. GALABIN considered immediate taxis by far the best treatment, although the gradual pessary method is valuable. He places the woman in the knee-elbow position and first from the vagina, then, if failing, from the rectum, applies the necessary manual pressure. In only five per cent. of all his cases has anesthesia been necessary. Twenty-five years ago, without admission to the hospital and in the out-patient room without anesthesia, he was accustomed to reduce this deformity and never found any trouble except in the above range of cases. Abortion had never followed immediate taxis, but the slow method. Special pressure pessaries, he thought, are best in maintaining a reduction when recurrence threatened or in completing a partial one.

A. H. Tubby, at the Society for the Study of Disease in Children, November 16th, exhibited an infant who at birth exhibited an imperforate anus and a rectovaginal fistula through which all the movements occurred. At the operation a probe was passed into the fistula and to the apex of the rectal cul-de-sac and exposed through an incision at the site of the normal anus. Then this incision was enlarged and the rectal mucosa was brought down and with some difficulty sutured to the lips of the cut. Unfortunately the stitches tore out and three months later the operation was repeated and succeeded admirably. No effort had been made as yet to cure the fistula itself. The same speaker also presented an angioma removed from a five-year-old child. It involved the whole left half of the scrotum as high as the external ring, was tough, inelastic, without impulse or translucency, reducible in size by firm continuous pressure, and corrugated on its surface as if by large deep varices. After removal it was found to be made of venous sinuses having their origin in the left corpus cavernosum near its root and imbedded in much connective tissue and fat.

G. Carpenter showed a three-and-a-half-year-old-boy who presented many subcutaneous fibrous nodules. There was no personal of family history of rheumatism, no cardiac lesion, only slight enlargement of the liver and spleen. The sites of the lumps were chiefly the extensor surfaces of the hands, wrists, feet and ankles. The first appeared during his second year of life at about the fourteenth month, and since November, 1898, while under the speaker's care, had increased in number. Galvanopuncture had decreased individual nodes, but nothing seemed to prevent the appearance of new ones. Radioscopy failed to reveal bone disease. He has seen several cases of such nodes not of rheumatic origin, but never in a child so young, nor so long under observation. Microscopically they consisted of fibronuclear tissue.

SOCIETY PROCEEDINGS

NEW YORK ACADEMY OF MEDICINE—SECTION ON PEDIATRICS.

Stated Meeting, Held Thursday, December 13, 1900.

Thomas S. Southworth, M.D., Chairman.

Dilatation of Colon.—Dr. William L. Stowell presented a patient suffering from marked dilatation of the colon, which had persisted for some seven years. The patient is at present a boy of nine years, whose history is about as follows: He was nursed until he was a year old and had reasonably good health. During his second summer, which came in the nursing period, he had very severe summer complaint. For a time his life was in danger. He seemed to recover completely, however. After he was weaned he was given more oatmeal and other starchy substances than usual, yet he suffered from almost constant constipation. This became more and more obstinate as time went by, and for the few years past he has not had more than an average of one stool a week.

When the patient first came under observation the abdomen was found to be greatly distended and the transverse colon stood out very prominently across the region of umbilicus. The bladder also was distended and there was a history of enuresis at night. When the constipation had endured for several days the boy became dull and did not respond to stimuli. This more or less comatose condition seemed to be the result of intestinal autotoxemia. Occasionally the boy passed some scybalous masses, but when the bowels were moved they were often semi-fluid in consistency, although very dark in color. There was no difficulty in securing a free movement of his bowels when he came under observation, although they had not been moved for eight days. A simple high injection sufficed to bring away a large amount of fecal material. What came away had very much the appearance of city mud, black and glutinous in character, semi-fluid in consistency and with occasional hard masses in it. Before the bowels were moved his abdomen measured 71 c. m. in circumference. After the movement it measured 60 c. m. at the level of the umbilicus, which is 16 c. m. more than in a normal child of his age and weight.

Problem of Etiology.—No very definite cause could be found for the condition. There was no stricture at the anus nor higher up in the rectum. Examination with a bougie as far up as the sigmoid flexure failed to show any obstruction. The rectal pouch was very much dilated. The blood count failed to show the presence of any chlorosis and the anemia was not very marked and was probably due to the constipation. The plausible theory for the origin of the dilatation of the colon seems to be that the muscle fibers of the large intestines became overstretched by the accumulation of feces and thus peristalsis was absent. Nothnagel describes an autopsy on one of these cases in which the thickness of the muscular wall of the intestine was found to be one-fourth that of the normal muscularis intestinalis. One extreme case has been reported in which the colon was so much distended that it was ten inches in circumference When this patient came for treatment the first thought was of some form of malignant stricture of the intestine. No symptoms of this could be found, however, and the fact that the bowels were moved easily by enema speaks against this theory of origin. The boy's family was not a dyspeptic one, there were no signs of nervous disease in members of the family, nor were they constipated. There exists some distention of the stomach in the case and this with the noc-

turnal enuresis seems to point to a tendency to relaxation of all muscle fibers in the hollow viscera. The treatment consisted of the administration of belladonna, strychnine and aloin, with the idea of toning up the muscular fibers. For the present at least the bowels will have to be cleared frequently by enemata. When the bowels are free from accumulated feces the boy is reasonably bright, and his condition shows that the mental dulness at other times is pathological and not natural.

In the discussion Dr. Koplik said that the appearance of the boy's abdomen was very like that pictured in a recent article of Dr. Murchison's. The distention of the upper abdomen was characteristically similar. When Dr. Murchison's patient was put under an anesthetic, the tumor disappeared and the doctor concluded that it was a phantom tumor. Here there is objective evidence of the accumulation of fecal material. The possibility of its exaggeration by nervous influences must not be forgotten. The fact that the stomach is also distended may prove an important factor in the case. The extent of the stomach dilatation should be carefully ascertained. As the patient's abdominal walls are thin, this could be determined by passing the gastrodiaphane.

Colonic Stricture.—Dr. J. J. Walsh said that there is at least one case on record in French medical literature in which a French army officer who lived to be fifty-four had a movement of the bowels not more than six to eight times a year. The condition began in earliest infancy and the patient was neither impeded in his career, nor did he seem to suffer any serious inconvenience from his unusual retention of feces. In this case it was found at autopsy that a valve-like membrane occurred just above the rectum, which practically occluded the intestine. Above this there formed an immense colonic pouch in which the accumulation of feces took place. When the amount of feces became excessive, the distention of the colon made the valve incompetent and the feces found their way past it. In the present patient it is not easy to escape the idea that the severe summer complaint from which the child suffered in its second year may have had something to do with the constipation which developed. A stricture high up in the descending colon, or near the splenic flexure might account for the condition.

In closing the discussion Dr. Stowell said that the most careful examination failed to reveal any evidence of stricture and that a large bougie could be passed easily up to and apparently beyond the sigmoid flexure.

Status Lymphaticus.—Dr. David Bovaird presented the specimens from a nursling who had died suddenly with enlarged lymphatic structures, lymph-nodes and thymus. The child was about four months old and was being nursed by its mother in a foundling asylum. It had never been ill. It seemed to be in perfect health when its mother put it down for a few minutes to go to breakfast. The mother had only just begun her meal when the nurse noted that the child was having a convulsion. Before anything could be done it was dead. At the autopsy it was noticed that the child was suffering from craniotabes. This softening and thinning of the skull-bones involved not only the occipital, but also the parietal region. The whole cranial vault was very thin. There was also slight enlargement of the epiphyses of the long bones.

The thymus gland was found to be very large. It covered the heart except for a small part of the apex and it reached down and was attached to the diaphragm. Both its right and left lobe were enlarged, the left more so. Moderate enlargement of the cervical nodes was found, and there was marked enlargement of the bronchial nodes. The mesenteric nodes were very much enlarged and the spleen was hypertrophied and soft in consistency. The solitary follicles all along the intestine were enlarged and prominent. Peyer's patches were moderately enlarged.

Thymic Asthma.—In the cases of sudden death in which the thymus was found to be as much enlarged, as in this case, the unexpected fatal termination was formerly attributed to the enlargement of the thymus alone. In recent years enlargement of other lymphatic structures has been found to accompany the large thymus so constantly that the latter is now considered an important factor in the fatality. The *status lymphaticus* is now set down by many pathologists as at least the predisposing cause to sudden death.

There are undoubtedly certain cases in which the thymus alone must be considered as responsible for the sudden death. In some of these cases a more or less lengthy period of difficulty of breathing precedes the fatal termination. Some cases in which dyspnea asserted itself very seriously have been relieved by removal of a portion of the thymus gland. There are many cases, however, in which absolutely no symptoms precede the sudden fatal issue. In these there seems every reason to think that the lymphatic enlargements are a contributing cause of death. The mechanism of the etiology is not known.

Thymus as Principal Cause.—In the discussion Dr. L. Emmett Holt said that there is scarcely any question in pediatrics on which more light is needed than this one of sudden deaths in infants. They occur with surprising frequency. When they occur in hospitals or institutions they do not produce the sensation that is usual in private practice. Dr. Holt has recently seen four cases that were somewhat similar to this one recorded by Dr. Bovaird. He is not convinced that the general lymphatism is of more importance in the production of the sudden death than is the enlargement of the thymus alone. It is not an unusual thing at autopsy on infants to find many of the glands enlarged. This is found very often in cases that have died a lingering death. In the sudden

deaths the distinctive feature at autopsy is the enlarged thymus. How this produces death is not clear. A distended stomach for instance pressing up against a heart already laboring because of the pressure upon it of an enlarged thymus may cause the organ to stop entirely. Sometimes the distention of the intestines with gas may furnish the accessory etiological element necessary for the stoppage of the heart.

Edema of the Brain.—Dr. Sara Welt Kakels said that she has recently seen one of these cases of sudden death in the Mt. Sinai dispensary. The little patient suddenly became cyanosed, threw its head back and died in its mother's arms. At the autopsy, edema of the brain was found, as well as general lymphatic enlargement and enlarged thymus. It is important to note very carefully then in these cases whether the edema of the brain may not be the direct factor in the production of the sudden death.

Bronchial Abscess and Sudden Death.—Dr. Dwight Chapin said that it must not be forgotten that there are other causes of sudden death in children besides the lymphatic diathesis and the enlargement of the thymus. Some of them are obscure unless careful autopsy is made. In the case of a child who died suddenly some years ago, while suffering from a slight bronchitis with an average amount of cough the death took place during a slight coughing fit.

Autopsy showed that the death was due to rupture of an abscess in the mediastinum. The abscess began in a bronchial gland which had broken down as the result of infection.

Lymphatism and Fulminant Infection.—Dr. James J. Walsh said that any one who saw several of these cases of the so-called lymphatic diathesis could not but be impressed with the fact that the enlarged glands might be due to some infective process. In fatal cases of infectious disease in children during the first two years when the thymus gland is active, the thymus is often found enlarged at autopsy. The opinion has been advanced that the presence of the thymus gland during the first two years of life makes infants less liable to contract infectious disease than after the disappearance of the thymus. One of the functions of the thymus gland seems to be the manufacture of leucocytes and the protective influence of leucocytosis is well known. The question occurs then whether these sudden deaths in children may not really be due to some fulminant infection that becomes generalized through the circulation. The enlargement of the lymphoid tissues throughout the body and also of the thymus gland would then be nothing more than a protective reaction on nature's part against the advance of the infection.

In closing the discussion Dr. Bovaird said that no dilatation of the stomach existed in his case, which might account for the accessory mechanical factor necessary to produce stoppage of the heart. Edema of the brain was not found, although this was carefully investigated. No abnormality, pathological, or congenital, of any other organ was noted, although scrupulous care was exercised in the examination.

Diagnosis of Infantile Adenoids.—Dr. Walter F. Chappell said that the diagnosis of the presence of adenoid hypertrophy was much more difficult in infants than in children of an older growth. There are objective and subjective symptoms. Among the objective symptoms are mouth-breathing, snuffling, the existence of chest deformity and the peculiar expression of countenance so common in these children. Among the subjective symptoms are difficulty of breathing, headache and slow development of the intelligence. Dr. Chappell does not believe that many children are born with congenital hypertrophy of the adenoid tissue of the pharynx. In the last few years he has examined 437 children, among whom 45 under the age of seven months presented symptoms of respiratory obstruction in the upper air passages. In none of these cases were adenoids present. In a large number of post mortem examinations on new born children he has never seen adenoids present. The fact that adenoids are not congenital is important since it enables us to realize that they are caused by certain pathological factors and that it is perhaps possible so to modify pathological conditions that the development of adenoids may be prevented.

Among the causes of respiratory obstruction found in infants were lymphatic and lithemic conditions, syphilis, congenital atelectasia of the lungs, high-arched palate, small postnasal space, the projection of the bodies of the cervical vertebræ into the pharynx so that the breathing space was very much narrowed, besides some rare anomalous anatomical conditions.

Other Simulants of Adenoids.—Congenital atelectasia of the lungs resembles adenoids quite closely when it is not very extensive. If there is considerable atelectasia present then of course the diagnosis is not difficult. Small amounts require the most careful examination of the chest to determine their presence.

The congenital high palate is a much more frequent source of difficulty of breathing than is usually thought. This is sometimes said to be associated with adenoids but may exist independently and the anatomical conditions of the soft parts associated with it interfere with the breathing.

Congenital hypertrophy of the tongue is not a frequent source of difficulty in breathing and yet it must be borne in mind. Dr. Chappell exhibited a portrait of a marked case of hypertrophy of the tongue in which there had been difficulty in breathing for many years. At times when the large tongue becomes actively engorged with blood and increases the respiratory difficulties, the application of a leech may do some good. Enlargement of the tonsils may cause mouth-breathing, snoring and difficult respiration. This will lead to the suspicion of the presence of adenoids, although they may not

be present. The differential diagnosis of the two conditions is important. Their confusion has undoubtedly led to the idea that adenoids are much more frequent in children than they really are.

Hypertrophic rhinitis is quite common in children and produces a set of symptoms resembling those due to adenoids. It must not be forgotten that this hypertrophy often accompanies adenoids and the discovery of one affection should lead to an examination for the other.

Adenoids in General Practice.—Dr. Frances Huber said that advanced cases of adenoids are very easy of detection. Small adenoid hypertrophy produces little symptomatic disturbance. When colds are frequent in children and with each cold there is an enlargement of the tonsils and some enlargement of the glands of the neck, adenoids will usually be found to be present. Difficulty of respiration in children should not be attributed lightly to anemia, or nervousness, but should raise a suspicion of adenoids. There are certain external symptoms that may also lead the practitioner to suspect the presence of adenoid hypertrophy. There is a form of trachoma without involvement of the cornea that is sometimes seen in connection with adenoids. There is a prominent vein at the root of the nose which may call attention to the adenoid condition. The persistence of enlargement of the cervical glands, or the frequent recurrence of enlargement is also a suspicious sign. Where frequently recurring attacks of nasal catarrh come on, adenoids should be looked for. Sometimes the little patient likes to throw its head back over the arm of the nurse, because this is an easier position for respiration these cases. Irrigation of the pharynx sometimes relieves the symptoms. Cases with crowing respiration especially just during and after feeding often have adenoids. The diagnosis should be made with the finger rather than the mirror.

Practical Treatment.—The most important measure for the prevention and the cure of adenoid hypertrophy is attention to the general health. During exacerbations of the difficulty of respiration nasal irrigation will often give relief. Marked symptoms of adenoid obstruction, however, if unrelieved by operation will usually leave permanent symptoms of nasal obstruction. For a week before operation is performed, irrigation of the posterior nasal space should be practiced. In irrigating no force should be employed, or otitis media will result. Operations should be done in the intubation position with a sheet wrapped around the patient, or with the head between the operator's knees. In Germany and France no narcosis is employed, but in this country many operators prefer to use either chloroform or ether, especially the former. Halstead of Syracuse uses ether and a small amount of atropine. In this way there is less vomiting afterwards. Evans of Louisville reports a death during the operation for adenoids when the anesthetic employed was nitrous oxide. As a rule the operation can be done without an anesthetic and even this risk avoided. If tags of adenoid tissue are left after the operation, it may be repeated. Sometimes these tags of tissue are not remnants, but are new growths of adenoid tissue, since the operation. Children suffering from the hemorrhagic diathesis, or that show a tendency to the formation of petechiæ should not be operated upon. If hypertrophy of the turbinate structures of the nose exists, as well as enlargement of the adenoid tissues in the pharynx, then all the symptoms will not disappear after the operation. These two conditions are associated oftener than is thought and their association is frequently a source of disappointment after adenoid operation.

Adenoid Simulants.—Dr. Koplik said that a number of conditions in children simulate adenoids and cause operations to be needlessly done. He has seen several cases of swollen tongue that caused the mouth to be open and so produced difficulty of respiration, that might lead a careless observer to think of adenoids. He has seen bony obstruction in both nares through which not even the finest probes could be passed. This was an anatomical anomaly and an operation for adenoids would have been absurd. Operation for adenoids is not as simple as is sometimes thought. In choreic children especially great care should be exercised in the operation. The removal of the lymphoid tissue opens up large absorbent spaces through which reinfection may take place and an increase of endocarditis follow.

Otitis Media and Adenoids.—Dr. Wendell Phillips said that assurance in the diagnosis of adenoids was very important. Ear symptoms are often present. Recurrent suppuration of the middle ear often means adenoids. A single attack may be due to other causes. Digital examination for diagnosis is inadvisable for two reasons—First, the finger is not properly sterilized, the adenoid tissue breaks down when touched and may easily be infected; the second reason is that the little patient always leaves the doctor's office his mortal enemy. Always examine with a mirror and tongue depresser and explain to patients just what you are going to do, even though they may be very young. Where adenoids are allowed to remain adhesive bands form, which often cause the orifice of the Eustachian tube to be permanently patulous and so predispose to ear trouble. Heredity is an important element in the etiology of adenoids.

Gift by Dr. Herman Knapp.—Deeds were recorded conveying to the New York Ophthalmic and Aural Institute the property adjoining its present building. The conveyance is recorded as the gift from Dr. Herman Knapp, who for many years served as the head of the staff of attending surgeons of the institution.

THE SOCIETY OF THE ALUMNI OF THE CITY (CHARITY) HOSPITAL.

Stated Meeting, Held October 10, 1900.

The President, W. L. Baner, M.D., in the Chair.

(*Concluded from page* 114.)

Osteo-Arthropathy.—The patient showed a photograph of his brother, whose finger nails were similar to his own. His father had died in mid-life of cholera. His mother was still living and in pretty fair health, although she is alleged to have rheumatism. The fellow had a somewhat bronzed skin, leading one to suspect Addison's disease, and where his collar and waist band had gone around his body, there were dark lines. He had during the speaker's service, a low run of fever, which one would expect with such a large abscess. His blood showed nothing but the leucocytosis which accompanies extensive suppuration. The pus from the abscess had been examined for tubercle bacilli, but none were found. In Hare's Progressive Medicine for 1900 it is stated that only 140 cases of acromegaly have been so far reported. So far as the speaker knew, there had never been a case of pneumonic osteo-arthropathy reported in this country. One writer had declared that it is really a form of acromegaly.

Dr. Carr thought it would be of interest to find out if the adrenals were affected. It would be well to watch the condition of the man's strength and vitality. It might be that he had enough tuberculous history to give him tuberculous disease of the adrenals. The question would come up as to what connection it would have with his bronzed skin.

Dr. Bissell stated that he used to find these club-fingers a symptom in the consumptive ward of Charity Hospital, and that they were there considered to be symptoms of heart trouble as well as of tuberculous disease of the lungs.

Dr. Newton said one did not see such broadening of the nails in an ordinary case of phthisis. They were somewhat curved. The terminal phalanges were spongy in appearance, judging from the skiagraph. He should have stated also that the internal condyles of both femora were enlarged, as well as both internal malleoli. But the maxillary bones and zygomatic arches were apparently not enlarged, as is usual in acromegaly.

Eustachian Catheter.—Dr. McAuliffe said that in using a nasal catheter with the conventional curve, it was sometimes impossible to pass it, owing to large turbinates or anterior nasal stenosis. In order to distribute this angle along the curve of the catheter, he had been experimenting for some time, and found that a curve like the one he presented would pass into the Eustachian tube where the ordinary one would not enter. He had been gratified to see how easily it passed. Most of the directions given for the passage of the Eustachian catheter contained the old rules that they must either hook on the septum or hook on the palate before rotating, and advance a trifle; but by guiding this catheter tip along the floor of the nose, as soon as it touched the descent of the soft palate, the instrument was turned, and by the pressure of this very curve against the septum it slid into place without going through the ordinary manipulations. In a nervous patient it sometimes was passed with twice the celerity as with the other curve.

Pregnancy in Both Cavities of a Bilocular Uterus; Abortion.—Dr. Brooks H. Wells reported this case, which occurred twelve years ago. Mrs. X., mother of several children and about three months pregnant, was examined by a prominent specialist at his office because of uterine cramps and bleeding. He found protruding from the dilated os an ovum, which he removed, packing the empty uterine cavity with gauze to control a rather free bleeding. On calling the next day, he found the woman having quite severe pains with some hemorrhage, and on removing the gauze an ovum presented itself. Rather surprised by this unexpected event, he removed the ovum with the finger and the curette, and found by digital examination what seemed a hole, the diameter of a finger, in the right side of the cervical canal. A sound passed into this showed that the patient had a septum dividing her uterus into two cavities.

Pregnancy in the Right Cavity of a Bilocular Uterus; Abortion.—Dr. Wells also reported this case. Mrs. B. S., German, stout, and a multipara, consulted him in June, 1890, for the relief of bleeding and uterine pains, and stated that she thought she was pregnant and aborting. Examination disclosed a uterus enlarged and soft, as if from a pregnancy of eight or ten weeks. The cervix was soft and patulous, and there was a slight bloody discharge. It was decided that the uterus should be cleaned out, but, on passing in a small curette and ovum forceps, only an empty cavity was found. Somewhat puzzled, he packed this cavity with a strip of sterile iodoform gauze and sent the patient home. Her pains continued and the next day he examined her under anesthesia and found an ovum protruding through an opening in the right upper part of the cervical canal. This ovum was removed with some difficulty and her pains and hemorrhage ceased. Both of these cases were of pregnancy in the more rudimentary horns of bilocular uteri, and are interesting because of the diagnostic difficulties they presented.

Dr. George H. Mallett agreed with Dr. Wells in his handling of the case. Lately he had rather wandered from the use of much gauze, as it blocked up the secretions rather than promoted drainage. Its only use was to increase the contraction of the uterus. A hot irrigating fluid would usually do that. Unless there was much hemorrhage, he did not use the gauze. Dr. Wells' solution of the case was probably the correct one, as it must have been a double uterus to sustain all the manipulation. He had known cases where sounds had been passed repeatedly, and still the patients have gone to term.

Resistance of Pregnant Uterus.—Dr. Alvah M. Newman reported a case to show what a pregnant uterus will stand at times. The patient was in the habit of introducing water by means of a fountain syringe whenever she became pregnant. At times it was successful; and it was never followed by any ill effects when she did not abort. Between the ninth and twelfth week of her last pregnancy she used about four pints of wood alcohol by means of a hard rubber syringe. The introduction was easy owing to a second-degree procidentia. The alcohol produced severe pain each time it was used (4-6 ounces), but no other ill effect. The speaker delivered her one month beyond the expected date of confinement of a large child. This delay may have been due to an interruption of development by the use of the alcohol, although it is quite possible that she may have made a miscalculation. Dr. Newton also referred to the case of a servant, who came last summer to New York and had an abortion performed. She returned to Montclair and was sick for several weeks in the Mountainside Hospital. In curetting the uterus, the speaker found a partition through its middle, showing a double uterus. With a curette he pierced what seemed like an inkwell, and evacuated a large quantity of dark blood. She was very septic for about six weeks and was in a bad way when she left the hospital. The speaker saw her a few days ago, and she seemed in fair condition, though not exactly robust.

Interesting Cases in Dispensary Practice.—Dr. William L. Stowell read this paper. (See Medical News, page 90.) Dr. Rupp said he hardly thought that the case of dermatitis exfoliata could be mistaken for erysipelas. As to typhoid fever in tenement-houses being catching, it was a good thing to teach the people *how* it is catching; that is, through filth. The doctors did a sort of missionary work by telling them to be clean. He spoke of one family, where there had been an epidemic. The brother and sister slept in a small room, not large enough for a single person to sleep in. These were both severe cases of typhoid fever. In regard to giving the coal-tar products, that depended on the sense of the man; he had seen two-grain doses in children produce cyanosis, but had never seen any harm done in giving antipyretics to adults or children, though sometimes people were frightened by it.

Dr. Newton thought the proper diet was the most puzzling thing in the treatment of typhoid fever. He lost a case two years ago. The patient was a young officer who came back from Camp Thomas, where they had so much typhoid. The day he died he had been given a raw egg, and had an attack of dyspnea followed by heart-failure, and the speaker thought perhaps this might have been due to indigestion. He had seen another case where eggs seemed to cause death, and had heard other doctors relate similar experiences. He had read an article on typhoid by an English writer, in which he cautioned every one to be exceedingly careful how they altered the diet in typhoid cases, saying that the slightest alteration might turn the scale in some severe cases, and might convert mild cases into severe ones.

Dr. Baner said that patients with typhoid fever were always apt to have relapses, and if they happened to have a relapse after being given solid food, it would be attributed to that. He had seen a number of cases in which the family undoubtedly always thought that death was caused by the patient having had solid food, generally some form of egg food. It was impossible to say whether it really had anything to do with the relapse. One of Dr. Stowell's questions was whether mustard baths shortened the duration of the inflammation. He had seen cases where undoubtedly giving a mustard bath increased the duration of the inflammation, as the lung was so much involved and dyspnea so great that it did not seem as if the child was going to live; a mustard bath lengthened the duration of the inflammation by saving the child's life. In regard to the coal-tar products, if properly used, as Dr. Rupp said, they were very valuable.

Dr. Carr said that lately a good deal had been added to the subject of how to feed a typhoid patient. One of the most recent was an article by Dr. Seibert, on the use of an exclusive soup diet. Dr. Seibert claimed very satisfactory results, both in adults and in children, by this method, basing his claim primarily on the fact that by the use of milk the number of bacteria in the intestinal canal was increased, and in that way there was not only a typhoid infection to treat, but the risk of other infections due to the milk. With soups there was less disturbance, because of less feeding material for the bacteria. He had carried out this treatment only partially, and in cases where soup diet was used at times in combination with milk, it seemed to relieve the flatulence and distention. In the use of an exclusive milk diet in typhoid, physicians would often give the milk rather thoughtlessly, as if the digestion of the typhoid patient was as good as one in ordinary health. Many people never digest milk well. If they took an exclusive diet of milk all day without any exercise, they would be flatulent, uncomfortable and constipated. If milk is given some care should be exercised for the state of the digestive organs. He diluted the milk or peptonized it, or gave koumiss or matzoon. He had never seen any bad effect from the egg as he gave it, the yoke beaten up with sherry wine. He spoke of an old physician whose favorite prescription was an egg emulsion, a mixture of wine and egg, a tablespoonful every two hours. He should question the advisability of giving a whole egg to any typhoid convalescent, because eggs sometimes caused indigestion. During convalescence in typhoid, the heart-muscle was weak, and any distention of the stomach and displacement of the heart, would interfere with its action and perhaps cause death. Dr. Peabody and other clinicians suggested some plans of treatment exclusive of milk. With reference to the typhoid in children, all recognized that it was apt to be less intense in its poison, run a short course,

and the percentage of mortality was low. Children did well almost invariably without much medicinal treatment. The important thing was to see that they were comfortable and treated symptomatically. They were more likely to be constipated than to have diarrhea.

Dr. L. Marcus said he happened to be in the service of Dr. Seibert in the hospital and could speak personally of the influence of a diet entirely of meat broth. The concentrated beef broth was given to the patients, and usually they were very comfortable and never gave any sign of tympanites. With regard to the cases in that same service under Dr. Lellmann, it was his rule to give every typhoid patient three raw eggs a day, and this was usually carried out from the first day of admission, unless the patient showed some disgust for eggs. He always gave milk, and the whole egg was beaten up in the milk. At that time (1897-98) the mortality was well under two per cent. Dr. Seibert relied entirely on antipyrin to reduce the fever. His form of treatment was to give five grains as soon as the temperature was up to 103° F., and after that kept giving five grains, until the patient's temperature dropped. The speaker never saw any patient suffer bad results from the drug, and they did not follow it up with stimulants until toward the end.

Dr. Bissell said he had heard nothing about the bath treatment. He thought that this was a standby in reducing the temperature of typhoid patients, and either tubbing or sponging was at once resorted to if the temperature rose to a specified point.

Dr. Stowell said these were tenement cases and there were no facilities for bathing, but in the hospital almost every one was bathed more or less.

Dr. Rupp gave his testimony with reference to eggs in typhoid fever. He never saw them do any harm. At present he had a patient, a young man nineteen years of age, who would not eat anything day, and they had no influence on the tympanites, but eggs, ate two or three soft-boiled eggs every The speaker impressed on him that he must chew the egg well and wash it down with water. It had no bad effect on the temperature. As Dr. Carr had said, there was a great deal of latitude in treating typhoid cases and one case could not always be treated like another. Some people would not eat at all. The soup treatment of Seibert, he did not think was anything new. Some Germans ate a great deal of soup. Virchow wrote a popular article some years ago saying that soups were not nutritious, and were not worth swallowing as nutriment.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held November 16, 1900.

A. B. Judson, M.D., Chairman.

Fracture of the Femur at Birth.—Dr. T. H. Myers presented a baby, one month old, under treatment for fracture of the femur just below the trochanter minor. The child was the second of twins and presented by the breech. The forceps failing, a hook had been used and caused the fracture with the very unusual displacement of the lower end of the upper fragment backward in spite of the tendency of the psoas and iliacus to pull it forward. The next day the child was in great distress. There was extensive ecchymosis at the seat of the fracture, ⅜ inches shortening, edema of the limb and eversion of the foot, and, on any slight motion, the muscles attached to the anterior superior spine were thrown into a marked spasm which drew the lower fragment forward. A plaster-of-Paris jacket was applied in which was incorporated a steel bar, ¾ x ⅛ inch, extending from the angle of the scapula to the toes, and bent at a right angle at the buttocks and the heel. Traction was made and eversion overcome by adhesive plaster applied to the limb and fastened to the steel footpiece. The plaster of Paris enclosing the pelvis provided secure counter-traction. A light plaster-of-Paris bandage secured the limb to the splint and held back the upper end of the lower fragment. A fenestrum permitted the dressing of the cord. The child fell asleep at once on this application which made after attendance easy and promoted the comfort and general health of the patient. No displacement. Shortening ⅛-inch.

Dr. V. P. Gibney said that fixation had been secured in an admirable manner. He asked why the limb had been flexed.

Dr. Myers replied that he had in that way sought to relax the psoas and iliacus muscles in order to reduce the unusual displacement. He had also seen a directly lateral displacement in a case of fracture of the neck of the femur probably caused by traction with the hook.

Dr. S. A. Twinch related the case of a child whose right femur had been broken at the junction of the middle and upper thirds in a difficult labor. The next day the limb was edematous and almost black. He had put the limb up in a plaster-of-Paris spica with the thigh flexed nearly at a right angle and the leg somewhat flexed. Eighteen days later the dressing was removed and the bone was found united in good position, but with considerable callus. He recalled a recently reported case of the same kind in which a good result followed retention in place for three weeks of a starch spica bandage. The patient had been examined when twenty years old, and it had been impossible to tell which leg had been broken.

Dr. G. R. Elliott said that the mechanical problem was how to secure apposition and fixation, a problem well solved by the use of a steel band and plaster-of-Paris, but capable of solution by easier methods as by the use of adhesive plaster.

Dr. A. B. Judson said that fractures in infancy usually united with great readiness and but little ultimate deformity.

Dr. H. L. Taylor said that when the femur was broken in so young a child deformity was not an

uncommon result, which he thought could not follow the method exhibited.

Dr. M. G. Campbell, of Atlanta, Georgia, commended the skill and care with which the baby had been treated which were in marked contrast to the too prevalent idea that nothing of importance could be done for one so young. Before pain had been relieved and muscular spasm overcome, rest had been impossible and feeding difficult, two things on which the welfare of a baby absolutely depends.

Dr. Myers said that a common method of placing the child in bed on its back and suspending the legs vertically made nursing difficult and did not control the position and secure immobilization so well as had been done in his patient, who lived at home and was conveniently carried to the hospital for attendance.

Incipient Hip Disease.—Dr. Judson presented a girl, seven years of age, with symptoms of disease of the left hip of twelve weeks' duration. There had been lameness and pain in the knee, the latter so severe that the child had to be lifted very carefully. Rheumatism was excluded. Night cries had followed unusual exercise during the day. Pain and lameness had been inconstant, recurring after intervals in which the child was apparently entirely well. General condition excellent. A diagnosis of hip disease had been made, in consultation with the family physician, on the above history, and the following signs which were observed October 25, 1900: Fulness of the left groin and flattening of left natis, the left gluteal fold more shallow than the right, left thigh and leg ½ inch and ¼ inch less in circumference than the right, and limitation of extreme motion in every direction with reflex muscular action. Limitation of motion was not found at the second examination, but reappeared at a later date. On presentation the child walked when the splint was off with no defect in her gait. When she was examined slight limitation of motion and reflex spasm were found by different observers on attempting extreme flexion, extension, abduction, rotation and abduction with reflex muscular action. Limitation of chiatic crutch had been applied November 15th, to be worn during the day with a high sole on the well foot, directly to relieve the limb from the labor of locomotion and the affected bone from bearing the weight of the body, and ultimately to permit resolution of the inflammation by natural processes. Prognosis: Absorption or incarceration of the focus in the cancellous tissue and recovery, after one year or two years, without deformity or any trace of disability.

Dr. Taylor and Dr. Myers recognized the presence of some of the signs of hip disease and thought that a positive diagnosis required further observation.

Dr. Gibney said that after the reported and present examinations he would give the patient the benefit of the doubt and consider the case as an incipient one, and, if changes occurred requiring more drastic measures, he would seek very seriously to overcome the reflex spasm by immobilizing or putting the parts at rest. If the perineal crutch could be relied on to give the hip rest enough so that resolution would take place, however small the focus or wherever located, the treatment was perfectly justifiable. He appreciated the importance of protection from weight and concussion, but thought that an apparatus which allowed pressure of the toe on the ground did not give enough protection to the joints, so far as reflex muscular spasm was concerned. He questioned whether it did not add to the reflex spasm to have the patient stepping on the toe and ball of the foot.

Dr. Judson said that the ischiatic crutch, as commonly worn, allowed the anterior part of the foot to reach the ground. The toe could be entirely removed from the ground by using a longer crutch and a higher sole, but this would lessen the ability of the patient to walk. He thought there was an important difference between concussion transmitted from the heel through a straight bony column to the affected joint and the same modified in transmission by the interposition and action of the ankle-joint controlled by the muscles of the calf.

Dr. Gibney thought that protection of the joint was not so important as relief obtained by preventing reflex spasm.

Dr. Elliott questioned whether the form of apparatus worn by the patient was sufficient in a patient having a good deal of reflex spasm.

Dr. Taylor questioned whether in a case presenting well-marked symptoms it would not be better to apply a splint with adhesive plaster to be worn day and night than to use an ischiatic crutch to be removed at night.

Dr. Judson said he had lost faith, if he ever had any, in the effect of apparatus designed to elongate contracted muscles or to arrest or prevent reflex action by a direct mechanical pull. Indirectly these important objects were gained by arresting the functions of the diseased joint, thus permitting abatement and resolution of the inflammatory action, which was the incitement of reflex muscular action. The latter ceased as soon as arrest of function brought about resolution. The two chief functions of the hip-joint were motion and weight-bearing, and the latter, carrying with it concussion, was more important as a factor in pathology and treatment than the former. The ischiatic crutch did not so thoroughly remove the weight of the body as putting the patient to bed, but the other advantages were obvious. It practically put the limb to bed and let the patient run about and go to school. In the painful periods of hip-disease the traction splint, combining the protection of the crutch with traction by adhesive plaster, was indispensable for the relief of pain by fixation.

Convalescent White Swelling of the Knee.—Dr. Judson presented a boy seven years of age, slowly convalescing under mechanical treatment for white swelling of the left knee. A year ago the patient's general condition was most unfavorable and locally there were sinuses surrounding the knee, great swelling and the usual evidences of a

disintegrating joint. His condition and the method of his treatment were (see MEDICAL NEWS, Dec. 30, 1899, LXXV, pp. 855, 856) described when he was presented to the Section on October 20, 1899, and the opinion was expressed that it was a case in which operative surgery should be practised in order to save life. Continued reliance, however, had been placed on the reparative natural processes assisted by mechanical treatment. In spite of the most unfortunate and discouraging environment, improvement had been marked generally and locally. The tumor was very much reduced and firm scars had taken the place of nearly all the sinuses. A year ago the child was emaciated and distressed, but, on examination, he was found to be well-nourished and comfortable. Treatment would be continued by a fixative brace worn day and night and an ischiatic crutch worn only during the day. Prognosis was still in favor of a useful limb, of good length, with no flexion and no deformity except a slight and unimportant degree of subluxation.

Dr. Elliott said that some of the swelling might be gotten rid of by systematic compression and drainage and removal of the tight band above the knee.

Dr. Judson said that the tumor of white swelling of the knee disappeared with the other signs and symptoms which yielded in due time to natural repair and restoration assisted by treatment. What appeared to be a tight band was that part of the fixative apparatus which made pressure from before backward near the joint in opposition to the counter-pressure made by the ends of the brace from behind forward at the extreme upper part of the thigh and lower part of the leg. There was no constriction or interference with circulation or nutrition at any point as no part of the brace was allowed to touch the posterior surface of the limb near the joint. The apparatus was a simple lever and any other arrangement of it would destroy the leverage which was relied on to arrest motion and reduce the flexion.

Dr. Taylor said that this result reminded him, by contrast, of the many patients whom he had seen with limbs disastrously shortened and deformed as the result of excision, an operation which interfered with the growing epiphyses, leading frequently to a shortening of 6 to 8 inches. He recalled an instance of this operation in which the result was complete dislocation of the tibia backward and a flail joint.

Dr. Gibney said that the best surgical practice omitted excision of the knee in children. He saw too many patients coming for the correction of deformity and almost hopeless disability, the result of excision. To save life amputation was required, in certain cases, but never excision in a child. He advocated a country branch to a hospital, open the year around, where children could be on a farm and have simply nurses and a physician or two to look out for them and do very few operations.

Dr. Judson said that the admirable plan thus outlined was too purely expectant. He would add thorough and painstaking mechanical treatment which, no less than good food and wholesome surroundings, reinforced the processes of recovery in growing children.

Dr. Myers said that general surgeons should agree with orthopedic practitioners in interdicting excision of the knee in children. He had kept a boy under strict observation for six years after his knee had recovered to prevent excision for deformity until he attained his growth. He returned from a vacation, however, to find that the patient had been sent to a general hospital where excision had been done at once with recurrence of extreme flexion with lateral deviation and the certainty of more shortening with further growth.

Cases of Funnel Chest.—Dr. Taylor reported the case of a girl, six years of age, seen in September, 1900, with a remarkable congenital depression at the lower end of the sternum, an instance of typical funnel chest of moderate degree. There were no evidences of rickets and the child's health was good. She was the fifth child in a family of seven. Her mother had the same deformity, but knew of no other cases in the family. This condition was usually attended by some displacement of the heart, but without impairment of circulation or respiration. Persons thus deformed had made fair athletes and soldiers.

Fatal Case of Abscess in Cervicodorsal Pott's Disease.—Dr. Gibney exhibited a specimen from a patient affected with Pott's disease with deformity. The girl, five years of age, had been treated as an out-patient by a head support for two and one-half years. The appearance of an abscess over the spinous processes of the last cervical and first and second dorsal vertebræ made it difficult to adjust the support properly and the child became an in-patient. Aspiration gave only partial reduction of the tumor and a sinus was established by an incision after which the child was going about the ward with the head support comfortably readjusted. In the afternoon of November 8, 1900, cyanosis appeared, was relieved when the patient was put in bed, but recurred during the night, when death seemed imminent. On November 9th, a tumor was found in the outer portion of the left cervical triangle with deep fluctuation. Pressure did not increase the flow from the sinus, but added to dyspnea. Traction by the weight and pulley failed to give relief. Attempts at exploration of the pharynx increased cyanosis. Under ether (3 drams) an incision two inches in length along the sterno-cleidomastoid exposed the carotid and a needle procured cheesy pus. With the finger between the carotid and esophagus a second sac was ruptured with the evacuation of four ounces of pus and some bone detritus. A drainage-tube was inserted. Respiration became easier. Temperature 104.4° F. in the afternoon. November 10th and 11th the patient slept fairly well at night, but with a good deal of coughing and had recurrences of difficult breathing and cyanosis during the day. The temperature fell to 100° F. After sleeping the early part of the night the patient died suddenly on November 12th at 3:30 a. m. Autopsy in the afternoon showed recent pleuritic adhesions with

normal lungs and abdominal viscera. The two abscesses did not communicate with each other directly. Cavities in the vertebral bodies communicated with the sac of the second abscess which extended along the anterior and lateral aspects of the vertebræ and downward behind the pleura and almost surrounded the esophagus. The pleural cavity was not invaded. There had been no paralysis. The cord was found to be pretty good in consistency all the way up. He had seen no less than six children die unexpectedly in the night with abscesses arising in this location from carious vertebræ. Autopsies had not made clear the cause of death.

Dr. Myers referred to the case (related at the meeting of March 18, 1898), of a boy, seven years of age, affected with vertebral disease in this location, and an abscess discharging in the posterior triangle, whose temperature, on repeated trials, rose when the boy was up and fell when lying down facilitated the drainage of the abscess.

BOOK REVIEWS.

CONSUMPTION: ITS NATURE AND TREATMENT, with a Chapter on Bacteria and Antiseptics. By WILLIAM H. SPENCER, M.A., M.D., Cantab.; M.R.C.P. London. Henry J. Glaisher, London.

THE CARE OF THE CONSUMPTIVE. By CHARLES FOX GARDINER, M.D. G. P. Putnam's Sons, New York and London.

NORDRACH AT HOME, OR HYGIENIC TREATMENT OF CONSUMPTION. Adapted to English Home Life. By JOSEPH J. S. LUCAS, Late Medical Registrar and Pathologist at North London Consumption Hospital. Simpkins, Marshall, Hamilton, Kent & Co., Limited, London.

ÆTIOLOGIE UND PROPHYLAXE DER LUNGENTUBERKULOSE. By DR. J. RUHEMANN, Berlin. Gustav Fischer, Jena.

EACH of these four little books is an index of the present-day views with regard to the treatment of tuberculosis. All of them insist on the necessity for plenty of fresh air, a liberal diet and symptomatic treatment. None of them rates any specific treatment for tuberculosis at any high value.

Dr. Spencer draws the conclusion that "the methods of practical medicine in the treatment of diseases, where bacterial agency has more or less part, are not to be limited to the use of remedies with a view to affect directly the micro-organisms themselves," and that "bacterial life and its consequences may certainly be arrested by changing the character of the bacterial soil and food and by changing conditions needful in order that a right use be made of the food. But this is not to touch bacteria, it is to touch their soil."

Dr. Gardiner discusses the treatment, not of consumption, but of the consumptive patient, an important distinction. His chapter on the pschycology of the sickroom should be read by every physician. It contains much that we all know, but are constantly forgetting. These sentences are pregnant with good suggestions: "It is often very pathetic to see the well-meant, but ignorant and awkward efforts of the family nurse in taking care of a nervous consumptive. A mother in her care of a son, urged on by love and a constantly wearing anxiety for his comfort and recovery, will, in season and out persistently wrap up, admonish, direct and fuss until her very presence becomes little short of torture to a sensitive boy."

Dr. Lucas' little book on Nordrach gives just those details with regard to the home life of a consumptive that it is important for the physician to insist on in his directions to patients—the regulation of windows, for instance, the temperature of living rooms, the clothing to be worn, with a special deprecation of chest protectors and mufflers, the food, its quantity, quality, and variety, with adequate details as to the diet and meal-times. Then, such subjects as the regulation of rest and exercise are treated in a practical straightforward way that cannot fail to be helpfully suggestive.

Dr. Ruhemann's book treats more especially of the important questions of the etiology and prophylaxis of tuberculosis. The influence of a preceding attack of influenza in preparing the soil for the tubercle bacillus is especially insisted on. The favorable influence which subsequent attacks of influenza have on the progress of the tuberculosis is brought out by some very interesting clinical data. Finally, the importance of sunlight as a prophylactic agent against the development of tuberculosis and as a curative agent in hindering the progress of the disease is made very clear.

THE INTERNATIONAL CLINICS. A Quarterly of Clinical Lectures and Especially Prepared Articles by Leading Members of the Medical Profession Throughout the World. Edited by HENRY W. CATTELL, A.M., M.D., Philadelphia. Volume III. Tenth Series. J. B. Lippincott Co., Philadelphia, 1900.

THE first fifty pages of the present volume of the International Clinics consists of a symposium on genito-urinary diseases. The articles on the treatment of soft chancre by Professor Alfred Fournier, of Paris; on extra genital chancres by L. Duncan Bulkley of New York, and on aseptic urethral instrumentation by Ferdinand C. Valentine of New York, are sure to be suggestive and valuable to the non-specialist. In the thirty pages devoted to therapeutics there are three articles of very practical interest—the use of digitalis for children by Charles Ross Jackson of New York; the treatment of typhoid fever in childhood, particularly by cold baths, by Professor Marfan of Paris, and respiratory gymnastics for tuberculous patients by Dr. Ferdinand La Grange of Vichy, France.

The subject of phlebitis always an interesting one to the general practitioner is treated suggestively from two different standpoints, by Professor Pinard, of the Bandelocque Clinic, and Merigot de Treigny, both of Paris. The latter discusses the important question, how long must a case of phle-

bitis be immobilized? The conclusion is that the average period of necessary immobilization can be fixed at six weeks, reckoning from the commencement of the last acute phase.

A valuable contribution from the pen of the late J. M. Da Costa of Philadelphia, includes the discussion of such interesting subjects as diphtheritic paralysis, arthropathy in lead poisoning and syphilitic liver. It carries with it the sad reminder that another of our great American clinicians has departed. Fortunately the record of his clinical work remains as a heritage for the present generation.

Dr. G. L. Walton of Harvard presents a good common sense discussion of the much-abused subject of degeneracy. He points out the anatomical, physiological and mental stigmata of the degenerate and gives a very conservative appreciation of the value of these stigmata as the basis for opinions in neurology. Certain of the articles in this number of "The Clinics" are more conventional than usual. Subjects are touched on too briefly to be enduringly suggestive, and there is a crowding of material not due to advised compression or to appreciative omission that detracts from the value of an otherwise very helpful volume.

Sanity of Mind. A Study of its Conditions, and of the means to its Development and Preservation. By David F. Lincoln, M.D. G. P. Putnam's Sons, New York and London.

This is an interesting volume of some 176 pages, nicely printed and well bound. It takes up in a semi-popular manner several topics which are always of interest to the follower of medicine and to the student of social science. The nature of mental derangement, degeneracy, education, self-education and social and civic duties are the several chapter headings.

There is nothing profound in the presentation, nor do we find anything that is new; in fact, the observations are thrown together in quite a helter-skelter manner, but withal the book is suggestive.

A Manual of Hygiene and Sanitation. By Seneca Egbert, A.M., M.D., Professor of Hygiene and Dean of the Medico-Chirurgical College of Philadelphia. Lea Brothers & Co., Philadelphia and New York.

The fact that a second edition of a handbook on hygiene and sanitation should be demanded in less than two years points to an interesting change in medical interest in recent times. This is expressed by the unselfish effort to promote sanitary measures so characteristic of the modern physician. It has given rise to the maxim that the medical profession is doing more than any other to put an end to its own usefulness. The feeling has become universal now that physicians must be able to direct patients how to keep well besides helping to the restoration of health when ill. The physician has a further duty to the community as well as to his own clientele in the cultivation of sanitary conditions. The growth of these feelings has made manuals of hygiene popular. Dr. Egbert's book of 425 pages is a clear, succinct and, as far as its limits will allow, a very complete résumé of modern hygiene. The subjects of ventilation and heating of water and its dangers, of food adulteration, and of school hygiene are especially well treated. Each of the subjects is taken up from a common sense, practical point of view that cannot fail to be of service to the practitioner. It is this that necessitates the second edition within so brief a period after the publication of the first. This will undoubtedly make this new edition sell as rapidly as the first.

Mental Affections. An Introduction to the Study of Insanity. By Dr. John Macpherson. Macmillan & Co., New York.

This volume consisting of less than 400 pages made up of the writer's lectures, extended and rearranged, is one of the most important contributions that has been made recently to the etiology of insanity and to the interrelationship of the neuroses, phychoses and diatheses. It is the work of a thoughtful, erudite mind and merits careful, close perusal and study, not alone by the student of psychiatry, but by the general practitioner, psychologist and sociologist. A glance at the table of contents conveys an idea of the scope of the work. Part I. contains chapters on Morbid Heredity, the Evolution of Insanity and the Determining Causes of Insanity. Part II. is taken up with a discussion of the Physiological and Histological Aspects of the Nervous System, Psychological Considerations and Pathological Symptomatology, including hereditary degeneration and cerebral dissociation. Part III. is devoted to Clinical Symptomatology and forms the bulk of the volume. Here the different forms of insanity are considered in detail, yet with notable absence of intricate classification, archaic nomenclature and prolix verbiage which unfortunately characterize many treatises on mental diseases intended for the general practitioner. The chapters on Insanity of the Degenerate is deserving of special commendation. The author is among the first of the British writers to convey the impression of an adequate and comprehensible grasp of the subject of paranoia. He discusses it under the title of Systematized Insanity in the Degenerate (Paranoia Degenerativa). The subject of Insanity with the Neuroses is less satisfactory, not only in manner of handling, but in conception and portrayal. Approached in a critical spirit there is much in the book with which to disagree, mainly questions of fact and belief based upon experience; but despite this the volume is a trustworthy guide for the student, a faithful exposition for the general practitioner and a highly suggestive, comprehensive account of the psychoses for the general medical reader.

BOOKS RECEIVED.

An American Text-Book of Physiology. Edited by Dr. W. H. Howell. Second Edition Revised. Vol. II. Muscle and Nerve; Central Nervous System; The Special Senses; Special Muscular Mechanisms; Reproduction. 8vo, 553 pages. Illustrated. W. B. Saunders & Company, Philadelphia and London.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVIII. NEW YORK, SATURDAY, FEBRUARY 2, 1901. No. 5.

SPECIAL ARTICLE.

AN HISTORICAL SKETCH OF THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

THE restless, fervid energy that impels men to teach has done more to supply our country with colleges than the anxiety of the public to learn. At the end of the first quarter of this century there was in Philadelphia a group of young medical men who felt the passion for imparting knowledge with no outlet for its exercise. The Trustees of the Medical School of the University of Pennsylvania, with that complacency which so often characterizes wealthy and successful individuals and institutions, declined to listen to the suggestion that the classes were overcrowded and that new developments were necessary; and there gradually arose two factions in the city, one claiming that a new medical school would draw more students to Philadelphia and increase the city's prosperity, while giving a chance to the talent outside of the University, and others vehemently protesting against the idea.

There was a nucleus of students in the classes which had been established by George McClellan and Eberle which formed the germ of the enterprise, and when the Legislature had repeatedly refused to grant a charter for the new school, McClellan solved the difficulty by proposing to organize a medical school under the authority of some literary college already chartered by the State. As a result of his efforts the Trustees of Jefferson College of Canonsburg, Pa., decided to open a medical department in Philadelphia, and thus was founded in 1824 the Jefferson Medical College which has since taken rank among the first in the country.

Six chairs were established, and a class of one hundred and seven students registered. But there was neither endowment nor building. The small, but ardent faculty, overcame this obstacle by renting a building which had been erected for a factory and altered into a theater, known as the Prune Street, or Tivoli Theater. Directly opposite was the old Walnut Street Prison, and what is now Washington Square was then the Potter's Field, so that the earliest *bon mot* of the new college was made by Dr. Atlee, a student of Jefferson's second class, who suggested that the young physician's struggles were typified by the debtors' prison in front and the paupers' burial ground at the side.

The first course of lectures opened in November, 1825. From the start the surgical clinic was a brilliant affair, and the material, as supplied by McClellan's practice, was a great attraction.

The first Faculty of the Jefferson Medical College consisted of men who, though able and full of ambition, were very young and who still had their reputations to make. Its members were enthusiastic, energetic, brave and honorable, with definite ideas, and not afraid to fight. It took a good deal of courage to cast one's fortune with this new school; the dominant sentiment was strongly against it and it involved a measure of professional ostracism.

The basic principle of the school was that it should be practical, that it should bring the student in contact with disease, and that it should endeavor to make him a practical physician and surgeon.

Dr. George McClellan, the real founder and the dominating influence in the school, was a

Geo McClellan

marked man even from boyhood; he was fierce, energetic, absolutely fearless, quick in conceiving, and rapid in understanding, always sure of his conclusions, very emphatic in his speech, and enthusiastic in anything he undertook. Of marvelous memory, he possessed a piercing eye, and a hand of iron steadiness. Graduating from Yale College in 1815, he studied medicine at the University of Pennsylvania, from which he graduated in 1819. Surgery was the preferred field of his early professional life and in 1823 he removed the entire lower jaw, the operation requiring but four minutes. In the same year he put forth his well-known views as to the arrest of hemorrhage in operations, and from these he never departed. He

was entirely opposed to the preliminary ligation of blood-vessels, and advocated the forcible tearing out of tumors, in order to lacerate the blood-vessels and thus prevent severe hemorrhage.

McClellan was the soul and spirit of the new enterprise. At the time the first class was ready to graduate, the Legislature had not as yet authorized the new college to issue diplomas, and the right to grant degrees was fought out in the courts of Harrisburg in the spring of 1826. Dr. Washington Atlee has recorded an anecdote of McClellan in this connection.

Dr. Atlee lived at Lancaster. He and several students were sitting in John L. Atlee's office in that town when a knock came at the door and an excited man rushed in. Dr. Atlee introduced him as Dr. McClellan of Philadelphia. Dr. McClellan told them he had driven the sixty miles from Philadelphia since morning, that he was obliged

Robley Dunglison.

to be in Harrisburg that night, that his horse was fagged out and could travel no further. Borrowing a fresh animal from Atlee he started at once for Harrisburg, making the entire one hundred and six miles within twenty-four hours. He obtained the charter next morning, arrived in Lancaster the same evening, changed horses again, and started for Philadelphia. When a few miles out from Lancaster the wagon upset. After much shouting, a farmer appeared with a lantern and began to ask how the accident had happened. McClellan shouted furiously, "Come, my friend, this will not do. Let us put our shoulders to the wheel and leave explanations until another time." The wagon was righted, and the next day the charter of Jefferson Medical College was in Philadelphia and the students were able to graduate.

The second commencement of Jefferson was held in 1827 when there were thirty-four graduates; the third was held in 1828, twenty-five men graduating. Among the latter was Samuel David Gross, who was destined to become the greatest surgical authority that this country has produced. After the third class had graduated it was determined that the school must be removed to better quarters. Dr. Ely, a distinguished Presbyterian divine, who was Secretary of the Board of Trustees, offered to fit up a building at his own expense and to rent it to the College for one thousand dollars a year. The offer was accepted, a building was selected on Tenth Street above Walnut, and in the Summer of 1828 the College was removed to its new quarters. In the first class graduated from the new building in 1829 was Washington L. Atlee—the Atlee the world came to know later as the celebrated authority on abdominal surgery, and author of "The Struggles and Trials of Ovariotomy." J. Marion Sims, known to all men as the founder of the science of gynecology, the inventor of the duckbill speculum, and the deviser of the operation for vesicovaginal fistula, graduated in the class of 1835.

The College grew apace. Every man upon the increasing staff was well known as a teacher and writer, the school was obliged to enlarge its quarters and was able, at last, in 1838, to secure an independent charter from the State, by which it became "The Jefferson Medical College of Philadelphia."

This prosperity was not, however, what had been predicted for the College, for the fame that characterized the early professors seemed to be foreign to the development of a brotherly spirit of getting on together. It was doubtless the eager restlessness of a group of energetic men working their way to distinction that caused friction and change. In seventeen years there had been eight different men in the chair of obstetrics, and so many dissensions had arisen and the students had so diminished in numbers that it was predicted that the College could never outlive its difficulties. Finally, in 1841, after a general upheaval that left every chair vacant, the Faculty was reorganized with a set of brilliant men whose relations toward the College did not change for fifteen years. As a result the school prospered to a degree surpassing any other medical college of the time.

In those days, which were such an advance in the medical teaching of the past, a two-year course of lectures, extending through the day and infringing upon the night, constituted the course of medical study. Badly-ventilated rooms, poorly-lighted lecture halls, crowded quarters, and practically no laboratory conveniences were the rule in Jefferson as in all colleges. The famous surgical clinic, which dated back to the days when Dr. McClellan brought his charity patients to the new college, had no adequate accommodations,

and patients who had undergone serious operations had to be sent to their homes in carriages.

Among the advance steps of improvement that took place before the middle of the century was the establishing of a small clinical hospital with fifteen beds in two rooms near the College. The professor of surgery began in 1835 to teach diseases of the eye in the dispensary, which was probably the first introduction of teaching that

JOHN KEARSLEY MITCHELL.

subject as a specialty in any American college. Oral examinations had been abolished in favor of written ones, to save time and secure the best results from panic-stricken students and to serve as records of the college work; and a spring course had been established to "raise the standard of education."

For a period of fifteen years, dating from 1841, the teachers of Jefferson College formed an harmonious and unbroken Faculty that was regarded as the ablest body of medical instructors in the United States. Every one of its members was a noted teacher and author, and a public-spirited, progressive man.

Among the most celebrated names were those of Dunglison, Mitchell, Meigs, Mütter, Pancoast and Gross; names that no student of the Jefferson can hear spoken without a feeling of reverence.

Robley Dunglison was an Englishman, a practitioner, and the editor of a medical journal in London, before he was elected to the chair of Institutes of Medicine and Medical Jurisprudence at the Jefferson. He was a widely-read and very learned man, and wrote a number of extremely successful books, among which his "Medical Dictionary" and "History of Medicine" are still standard works.

John Kearsley Mitchell, the Professor of Theory and Practice of Medicine, was a successful practitioner, a literary light, a poet, a scientific chemist, an excellent teacher, an impressive orator, a medical philosopher—in short, an extraordinarily-gifted man. He first suggested the nervous origin of rheumatism, indicated the value of rest in spinal troubles, and, in 1849, wrote a famous essay on the "Cryptogamous Origin of Malarious and Epidemic Fevers," in which he clearly anticipated modern science in the view that fungi cause febrile maladies, and there is little doubt that he saw the plasmodium of malaria. His son, Dr. S. Weir Mitchell, the distinguished *literateur*, physician and scientist, graduated from Jefferson in 1850.

Charles D. Meigs, the Professor of Obstetrics, was a famous lecturer, having at his command wit and learning, combined with dramatic power and pathos. He was a man of lovable eccentricity, with a genius for description and anecdote. It was he who gave the name of "milk-men" to those writers who believed that puerperal insanity, abscess in the breast, and other disorders of confinement were due to absorption of the milk.

Mütter received part of his medical education on the Continent, and through him orthopedic surgery and the foreign methods of plastic surgery were introduced into the United States. It was in his clinic in 1846 that ether was used as an anesthetic for the first time in Philadelphia, and

JOSEPH PANCOAST.

it was he who introduced the practice of "quizzing" into the College.

Joseph Pancoast who held the chair of Anatomy and divided the surgical clinics with Mütter, was universally regarded as the greatest operative surgeon in this country. In fact, his reputation was international, as was shown by the fact that the daughter of the Lord Chancellor of England was sent to him to have a difficult operation performed. Pancoast executed the most formidable operations with a dash and speed and certainty simply amazing. He devised numerous operations which still bear his name. He invented the abdominal

tourniquet, the tongue-and-groove suture, a method for making a new nose, a method for curing exstrophy of the bladder, and a method of removing the nerve trunks from the face for the cure of neuralgia. What we know as the bloodless method of Esmarch, was really devised by Pancoast, and was practised for years in the Jefferson Clinic.

John J. Black, in his reminiscences of forty years ago, describes Pancoast as he appeared to him in his youth. "He was a large thick-set man with a kindly manner. His hand, that organ which did so much for him and for humanity, was large, heavy and thick, with immense, blunt fingers; any other than a hand you would look upon as facile and dextrous almost beyond belief. He could do a major operation, as a hip-joint, and pass with graceful ease to a case of cataract. It was wonderful how he could use those great blunt fingers. They could turn and twist and reach anywhere. His audience was always *en rapport* with the man and his patients looked upon him as next to divine."

The great operations at clinics in these days were those for stone in the bladder, the tying of the larger blood-vessels, amputation at the hip-joint, removal of tumors, etc. One can almost transfer oneself, with the help of Dr. Black's memory, to the amphitheater of the Jefferson Clinic in the early sixties and witness the dramatic effect of an operation by Dr. Pancoast for sarcomatous growth of the thigh.

"There was a large audience present of physicians and students. Dr. Gross assisted at the operation. Both he and Pancoast had something to say. Pancoast's address was quite pathetic; he spoke of the gravity of the operation and its uncertain ending for the patient, said she had seen her clergyman, had had the last rites of her church, and trusted herself to her surgeon and to her God. After the ether had been administered, which was done after the preliminary examination and explanation of the case had been gone through with, the abdominal tourniquet was applied by Pancoast himself. He spoke of its uses, and said, 'Gentlemen, *there will be no hemorrhage.*' He then took his place with nothing but a large scalpel in his hand. Gross stood by him and Maury had charge of the limb. 'Now, gentlemen, are we all ready? Maury, you are a good fellow. I depend on you; when I say lift, you lift; when I say lower, you lower; when I say right, move the limb to the right; and left, move to the left.' He commenced by making first an anterior skin-flap, then a similar posterior one, then a circular incision of the muscles, completing the operation by dislodging the head of the femur, without once stopping or laying down the knife. There was no bleeding, and the securing of the vessels and the dressings completed the brilliant operation. The patient made a good and rapid recovery."

In 1866-67 the clinical opportunities were much enlarged by the establishment of a daily clinic in charge of Dr. J. M. Da Costa, and a "summer course" was started. The crowding of the clinic and the great number of surgical operations performed in cramped quarters, as well as the renewed enthusiasm of the students after the war, led finally with the help of the Alumni to a State appropriation, followed later by a second, together aggregating two hundred thousand dollars for the purpose of enlarging the college and hospital buildings.

The prosperity of the College kept pace with its accommodations. In 1877 the new hospital was finished, with beds for 125 patients and a fine operating amphitheater that would seat more than 700 students. The new laboratory building was the next step, providing room and equipment for the study of practical chemistry, microscopy, physiology, materia medica, and pharmacy.

At that time the statutes of Pennsylvania, like

S. D. Gross

those of most American Commonwealths, contained stringent laws against the desecration of cemeteries, and it was almost impossible to legally procure material for the proper study of anatomy. The absolute necessity for dissecting was recognized, however, by every educated person. Through the exertions of the then demonstrator of anatomy at the Jefferson Medical College, a perfected bill was finally passed by the Legislature, under which not only were dissections legalized, but provision was made for the distribution of all unclaimed dead bodies to the various medical colleges in the interests of science. This triumph was accomplished at the expense of much sensational scandal and personal persecution, but the persistent efforts indicated above brought

about the present more enlightened legislation that has broadened all medical study.

In 1885 a maternity department was organized in connection with the hospital. This is complete in every respect and in charge of the Professor of Obstetrics. The advancing standards, a sign of progress in all college life, began in 1882, when the course of two years was successfully increased to three, simultaneously with the organization of a corps of clinical professors to give practical instruction, particularly to the third-year class.

In 1890 the requirements for preliminary examinations were raised, and in 1895 the compulsory four-year course was established, accompanied by many changes in the scheme of study, necessitated by the advance of medical science in its untiring effort to discover all the phenomena of disease by exact laboratory investigations.

About this same time the Trustees determined to change the financial policy of the college by placing the Faculty under salaries, and assuming the entire material administration of the institution. This radical change met with the approval of the Faculty, who submitted to a reduction of their income in order that they might assist the Trustees in their efforts to place this school in the position to which it was entitled. From this action dated the renaissance of Jefferson. Dissensions ceased and the teaching body, unfettered by the responsibilities of non-medical questions, devoted themselves exclusively to their noble avocation.

The Hospital, situated in the heart of Philadelphia, was an outgrowth of the need for clinical facilities, and has been one of the causes of the great success of Jefferson Medical College. It has at its command the services of a small army of leading practitioners of medicine, surgery, and the specialties, and the wealth of clinical material is so great that in its last report over 99,000 annual treatments are recorded. It constantly draws difficult cases from the city and surrounding country and the most distinguished operators from home and abroad take part in its clinics.

The College which in 1826 had but six, now has twenty chairs, and a total teaching staff of 137 members, comprising professors, assistants, demonstrators and instructors. It also possesses ten large laboratories and seventeen smaller rooms for individual research to properly prepare its more than 750 students to fight disease and death. With its splendid teaching staff, its superb facilities, the liberal policy of its administration and the enthusiasm of its followers, Jefferson Medical College is accomplishing the most difficult task of excelling the great achievements of its past, thus insuring for itself a still more glorious future.

Another Antityphoid Serum. According to *Wiener Klinische Wochenschrift*, Dr. Jaz of that city has obtained some excellent results from a new antityphoid serum. It is reported that in the wards of the general hospital it has been used on fifty cases with excellent results. Treatment is by the mouth.

FATTY DEGENERATION OF THE HEART.*

By THOMAS E. SATTERTHWAITE, M.D.,
OF NEW YORK;
CONSULTING PHYSICIAN TO THE POST-GRADUATE, ORTHOPAEDIC AND BABIES' HOSPITALS.

Fatty degeneration of the heart was first correctly differentiated from the fat heart of obesity by Laennec[1] and a little later by Andral[2] who called it *ramollissement du cœur*. Laennec in calling attention to the yellow or "dead leaf" color of fatty degeneration referred to the advanced stages of fatty degeneration.

The source of this degeneration appears to have been discovered by Hayem[3] at least so far as typhoid fever is concerned. In 1883 Germain Sée[4] confirmed this view, while in 1891 E. Romberg[5], after an elaborate study of the heart substance in typhoid, scarlatina, and diphtheria, discovered in all of them a granular and fatty degeneration of the heart-muscle, together with a small-celled infiltration of the adjacent connective tissue. In 1898 Bollinger[6] adopted this view and described three degrees of fatty degeneration, though he did not intimate that they might be three stages in the one process. In the same year Dehio[7] confirmed Hayem's views, so that we may now regard the matter of fatty degeneration of the heart as fairly outlined pathologically. It remains for us to attach, if possible, clinical phenomena to the successive stages of its development. Fortunately we appear to have the data at hand for this purpose.

It is very important to put this matter on a sound clinical basis, for how often does sudden death by heart-failure strike down a person who, up to the time of the attack, appeared to have excellent health. In fact, his physician may have examined his heart and, finding no signs of valvular disease, have been content with the diagnosis of a "weak heart," and yet the heart-substance may have been so profoundly diseased that it only needed a sudden, violent, or even prolonged "strain," to cause hyperdilation and cardiac paralysis.

I described such an instance at a meeting of the New York Pathological Society some years ago. A gentleman, seventy-one years of age, after leading an active life up to a year before his death, was suddenly taken with dyspnea after some hill-climbing in California. Up to this time he had never had heart-symptoms. He recovered promptly, however, from this attack. Later he took a 25-mile sleigh-ride and had another attack, but was restored by stimulants. Five weeks before his death he lost consciousness in a street-car, and was taken home with some difficulty. However, stimulants again revived him. An examination by the family physician showed that he was anemic and weak. The pulse could not be felt, and the apex beat was barely appreciable. He did not rally. At the postmortem examination which I made there was a marked blanching of the surface

*Read before the Medical Society of the State of New York, January 29, 1901.

of the body. The lungs were edematous and the kidneys pale and fatty. The heart was not especially enlarged, but it was pale and flabby.

Microscopic examination of the cardiac muscular tissue showed that along the inner wall of the left ventricle the striations were quite gone, though they were fairly well marked at the periphery of the ventricle. There was no valvular disease. In this patient the initial "strain" to the degenerate heart-muscle seemed to be traceable directly to the hill-climbing in California. There were apparently no other lesions to cause death.

The weak heart of fatty degeneration is common enough at all periods of life. In infants and children it occurs during and after the eruptive fevers, diphtheria, acute rheumatism, pneumonia, influenza, or, in fact, any acute attack of fever or toxemia. In senility, at whatever age it may happen, whether early or late in life, it is a phenomenon to be expected. In fact, whenever there is a prolonged fever, toxemia, dyscrasia or mechanical injury, fatty degeneration of the heart may occur. With few exceptions, the so-called "weak heart" is in reality the heart of fatty degeneration, and whenever death is traceable directly to heart-disease the actual cause of death is most often associated with the yielding of the cardiac walls.

And yet, to judge from individual experience as derived from intercourse with physicians and from current literature, the matter is not so understood by the profession at large. In consequence the degeneration is apt to be recognized too late for treatment, as in the case just cited.

It will be the province of this paper to discuss the etiology of fatty degeneration and to point out that it may be separated for practical purposes into three stages, each characterized by definite clinical signs; and to indicate the line of treatment appropriate for each stage.

The early or preliminary stage is the one in which the prognosis is the most favorable for complete recovery; in the second or intermediate stage we should be able to hold the disease in check; in the third or final stage palliative treatment alone is possible.

If, however, we are to grasp the matter intelligently, we must first of all look to the minute structure of heart-muscle. Though involuntary, it is made up, as we all know, of muscle-cells marked by longitudinal and cross striations. The body of each cell is cylindrical and contains one or two nuclei. The nucleus is vesicular and oval and is placed near the center of the cell-body. The cells are not only joined at their ends with contiguous cells, but, through branches with other cells, making in this way a reticular network. The apposition of these cells is effected by a cement substance that is not seen under ordinary conditions, and the network holds in its meshes vessels, nerves and fat.

In inflammation of this muscle the cells become opaque, owing to their infiltration with granular matter, or at least with something presenting that appearance (cloudy swelling), and the particles have been thought to be *albuminoid*, because they disappear to some extent with weak acids or alkalies. A theory has been proposed that this *albuminoid* material may be formed from the cytoplasm of the cells.

Another theory supposes that the granules represent the toxic elements of disease; another that they are effete matters being eliminated; another that they are micro-organisms; another that they are fatty particles in a stage of minute deposition. It is certain that some of them are pigmentary, from which it follows that all of them are not of the same character. It is also certain that in many instances, such as acute phosphorus-poisoning, arsenic poisoning, and typhoid, many of the particles in the first stage are either mainly fatty or of some substance closely allied to it.

In the second or intermediate stage, the muscle-cells are dotted with larger globules of oil and appear to occupy the same position as the "albuminoid" and fatty particles of the first stage.

In the final or third stage, the fatty globules reach a higher degree of development, while occasionally the muscle-cells are pulled apart (segmentation), or broken into fragments (fragmentation), as the result of hyperdilation. In this stage there is an engorgement of the blood-vessels of the internal viscera, limiting their functional activity and causing hyperemia, edema, thrombosis or embolism. Renaut[8] has gone so far as to classify segmentation as a variety of chronic myocarditis, which he has called *myocardite segmentaire chronique*. This view met at first with opposition from Ziegler and Recklinghausen, who regarded segmentation as an agonal manifestation. Hektoen[9] of Chicago, however, has examined eighty hearts to test the matter, and has come to the following conclusions: Segmentation and fragmentation do occur in heart-muscle during life in consequence of irregular contractions or injuries, usually associated with disease of heart-walls. If the segmentation or fragmentation is limited in area it is not immediately fatal. Consequently we are forced to believe that both segmentation and fragmentation are real events in heart-strain, contributing of course to the fatal issue.

Reverting for a moment to the subject of the so-called albuminoid change, a theory has been advanced that in exhausting diseases associated with prolonged fever in which the cardiac muscle is actually starving from lack of nourishment, in its hunger it makes a demand on the store it has already accumulated, *viz.*, the metaplasm of the muscle-cell; but if this is exhausted and more is needed, it is compelled to consume its own substance. Now, the reserve stock in the meshes of the muscle-cells is made up of carbohydrates, and there is no harm done to the cell by this consumption. When, however, the living tissue of the cell has to be sacrificed there is a loss of the proteids or albuminoid substances of the cell and the damage done is directly proportionate to the amount consumed, and yet the combustion is incomplete, a granular *débris* being left behind in the cells. But consumption may proceed a step

further, so that the fatty matters and fluids of the protoplasm are burned, though the combustion is still incomplete, and a further residue of oil is left behind in the cells. And yet even now a restoration of the cells is possible, provided only the nucleus has been left unimpaired. Death of the nucleus, however, means death of the cell.

Quite a different view has been presented by Huchard[10]. It is that the first stage of fatty degeneration is due to the irritation of a micro-organism or toxin, which, if sufficiently virulent, causes inflammation and possibly necrobiosis of the cell ultimately. This last theory is plausible, but it does not apply to the fatty degeneration seen in retrograde changes, such as occur to the parturient heart, the athletic heart and the heart of adherent pericardium, in which the fatty degeneration of certain portions of the cardiac walls appears to be due directly to lack of use, for when certain fibers are no longer needed, they are pretty sure to degenerate and eventually disappear. So much for the theories of the production of fatty degeneration. Accepting the dicta of Hayem, Romberg, Huchard, the acute stage is essentially a fatty one, that is, the acute softening in typhoid, scarlatina and diphtheria.

Fatty deposition or accumulation in the heart, the fat heart of obesity, is quite another condition etiologically and pathologically. Fat accumulates in the connective or interstitial tissue lying between the muscle-bundles. It is the result of overfeeding either with fatty food, or any food material that is in excess of bodily requirements, but the two processes are to some extent allied clinically for the muscle-tissue may suffer atrophy in the fat heart from pressure of the fat tissue, or the fibers may be so separated or overstretched that their integrity is impaired and they will degenerate in consequence. Fatty deposition and fatty degeneration may, therefore, coexist in the same heart, and yet while fatty deposition is apt to cause fatty degeneration, fatty degeneration never causes fatty deposition.

To the naked eye there is little difficulty in recognizing fatty degeneration by its pale yellow color, well shown beneath the lining membrane of the left ventricle or papillary muscles in nearly every heart in which there is chronic valvular disease, but the eye will often fail to recognize it in the softened heart of typhoid fever or diphtheria, for the tissue will not be yellow, but of a muddy, brown color, or, if there is a fibroid element, the color may be violet-brown or violet. It occurs in localized areas presenting a mottled appearance, or is diffuse and the special area of softening is "mushy," so that in handling the heart the fingers sink into it. The left ventricle is chiefly affected at first.

Fatty degeneration taken in the broad sense that I have indicated must be quite frequent. Roemer of Tübingen, between 1870 and 1890, had at his clinic 291 cases of valve lesion, in which 230 showed symptoms of disturbed compensation, while at the same time there were 234 cases that he called myopathic heart-failure, without any lesions of the valves. Now, as most of these 234 cases were really fatty degenerations, heart-failure without valve lesions was about as common as heart-failure with valve lesions.[11] Chronic fatty degeneration of the heart is usually associated with cardiac hypertrophy, atrophy, fibroid disease, fatty deposition, chronic endo- and pericarditis, and some other cardiac diseases. For example, Quain found hardening or calcification of the coronary arteries in 13 out of 33 cases of fatty degeneration; Markham in one out of 12 (Whittaker), so that arteriosclerosis may also be regarded as one of the causes of fatty degeneration. It is an unfortunate idea prevailing in some quarters that coronary disease has a preponderating etiological connection with fatty degeneration, but such is not true, and it is not at all uncommon for me to have a case of fatty degeneration turned over to me with the label "coronary disease." With other physicians I might add the term "myocarditis" means fatty degeneration. Sobernheim, who introduced the word myocarditis in 1837, deserves no credit for so doing, for it supplanted the word "carditis" introduced by Corvisart, and a much more appropriate term.

We usually meet with the chronic variety of fatty degeneration in middle life, and this has been my experience, though it may occur at earlier periods of course. In 88 cases published by Hayden[12] fatty degeneration was found most commonly between sixty and seventy, less often between forty and fifty years of age.

It is extremely important that we recognize the early or premonitory stage, as bearing both on prophylaxis and treatment. Unfortunately this is not always possible. In mild cases the physical signs may be absent, for there may not be any dilatation, and the physical signs depend on this circumstance. Hence the importance of outlining the heart by percussion, variations in outline from the standard will indicate whether the right or left ventricle is dilated, and the position of the apex will aid greatly in determining whether the heart is enlarged. Then the impulse at the apex will be more or less feeble, and the pulse will be intermittent and rapid. The sound of the heart will also be weak. There may not be any murmurs, or, in the absence of valvular disease, there may be systolic murmurs due to muscular insufficiency. If there is hypertrophy of the right ventricle following dilatation of the left ventricle, there will be an accentuation of the second pulmonary sound.

There may also be precordial pain or distress and spells of dizziness or fainting. This stage may last a few days, weeks, or months; or longer after diphtheria and influenza. A few cases taken from my pathological records while pathologist to the St. Luke's and Presbyterian Hospitals, illustrate the subject of fatty degeneration.

Case I.—A drinking man, thirty-eight years of age, entered the hospital with an empyema, the abscess discharging in the mammary region. Pulse 100; respiration 31 to 36; temperature 102° F.; dyspnea, precordial pain, cough, mucous expectoration and night-sweats. After battling with

the attack for three months he died of cardiac paralysis. At the postmortem examination the opposing surfaces of the pericardium were found to be acutely inflamed and were "hairy." The pericardial sac contained three ounces of clear serum. The heart was dilated and in a condition of acute softening. Fifteen ounces of purulent fluid were taken from the pleural cavities. This was an example of fatty degeneration of the heart in the first stage due to a combination of two causes, acute pericarditis and empyema. The cardiac symptoms were not clear, being obscured by those of the empyema.

Case II.—This also illustrates fatty degeneration of the first stage in a marked manner. M. C., thirty-two years of age, widow, stewardess, was admitted to the hospital July 25, 1879, with yellow fever. Her illness dated back only five days, when she was taken with frontal headache and general "soreness" of back and legs. The initial chill was followed by nausea, diarrhea and fever. Pulse 108 and weak; temperature 105° F. On the ninth day she vomited dark matter, became delirious, had albumin, 50 per cent. by volume, with scanty water. At the postmortem examination the heart was found to weigh ten ounces and was soft, flabby and fatty. The valves, however, were free and normal. This fatty condition of the heart had previously been noted by Dr. H. D. Schmidt of New Orleans, as a characteristic of yellow fever, with at the same time fatty degeneration of other internal organs including the brain. This case I regard as another instance of fatty degeneration in the first stage. I made the microscopic examination of the heart.

In the second stage the signs of a dilated heart are more pronounced. The left ventricle may reach to the left nipple or beyond it, while the right ventricle may extend an inch or more beyond the right border of the sternum. The apex may be in the fifth, sixth or seventh space. The pulse will usually be soft, intermittent and slow. There may be and often is a lack of balance between the heart and pulse-beats. There may be a reduplication of the heart-beats. There is one class of patients not infrequently seen in this intermediate stage. They are persons for the most part who have passed middle life, are inclined to be stout, though not always so, but are anemic in appearance. The pulse will be slow, intermittent and feeble, the apex beat hard or impossible to locate by palpation. They will have dyspnea, some precardial oppression, with occasional attacks of dizziness. Gastric symptoms are always in evidence, and occasionally there will be gastric crises alternating with anginoid attacks. Cyanosis will occur a times. Such patients will usually be irritable or whimsical or nervous about trifles, but always concerned about their health. There will be a disinclination to undertake anything new, even to walk, and the gait will be uncertain. Occasionally there will be hemorrhages, usually in the form of epistaxis. Local edema of face, hands and feet will occur at times. The urine will contain a little albumin, and often a little sugar. This stage may last from two to three to ten or fifteen or twenty years, depending largely on the degree of the degeneration and the care the patient takes of himself. I have under my care at the present time several cases in this stage.

The third stage is ushered in by symptoms that indicate secondary implication of other organs. There may now be pseudo-apoplectic attacks, due to cerebral embolism or thrombosis referable to imperfect heart-action. Attacks of heart-failure are more frequent and more alarming. Albuminuria is more pronounced and less amenable to treatment. In fact, symptoms referable to chronic nephritis are the rule. Gastric disturbances become so pronounced that the patient is afraid to eat for fear of the distress it occasions. Local edema passes over into general. Thrombosis of veins may be a pronounced feature. In one of my cases thrombi distending the right external jugular were distinctly felt. A low form of meningitis from effusion at the base may be one of the final events. The mind will be disturbed and there may be Cheyne-Stokes breathing at times, though this is not necessarily a sign of immediate dissolution. But until stasis occurs in internal organs, we should not despair. When, however, it occurs, and this condition characterizes the third or final stage, the end cannot be far off. With great care life may be prolonged a few months. Death may occur, however, not from any of the above causes, but from rupture of the heart. Quain has seen it in 28 out of 83 cases.

This stage is illustrated by the following three cases:

Case III.—A man, forty-six years of age, entered the hospital with signs of general syphilis. He had cough, jaundice, dyspnea and swollen feet. A soft systolic murmur was heard at the apex. The patient died fifteen days after admission of chronic nephritis. At the postmortem examination, the pericardial sac was found to contain ten ounces of clear serum, and there were several milk patches on the heart. It weighed eighteen ounces. There were no valve lesions. The liver was large and fatty. The kidneys were the seats of chronic nephritis. At the autopsy the murmur was held to be muscular and due to fatty degeneration of the heart. Syphilis was pretty certainly the remote cause of the fatty degeneration.

Case IV.—The following is another of my cases: A woman, thirty-eight years of age, who said she had suffered from "malaria," was admitted to the hospital with edema of the lower extremeties. She complained of attacks of palpitation, with precordial pain, tonic spasms, and dyspnea. The pulse was intermittent and the aortic second sound accentuated. The patient died of cerebral hemorrhage. The autopsy disclosed general arteriosclerosis with chronic diffuse nephritis. The heart was dilated and soft, but the valves were free and sufficient. The cause of the fatty degeneration in this case was arteriosclerosis, and the death by cerebral hemorrhage illustrates one of the several ways in which the end comes at last.

Case V.—A woman, sixty-three years of age, with a history of articular rheumatism, was ad-

mitted to the hospital with cough, hemoptysis, dyspnea and chronic nephritis. She had a systolic murmur over the apex, and also over the aortic and pulmonary areas, with accentuation of the second pulmonary sound. She died of cardiac paralysis and chronic nephritis. At the autopsy the heart was found to weigh twelve ounces. The valves were free and sufficient, but the cardiac walls were soft and flabby, and the cavities of the heart were dilated. The heart and pericardium were united by an old adhesive pericarditis. The liver was large and fatty. In this instance we have the fatty degeneration of the heart always found in adherent pericardium, though the toxins of rheumatism may be assumed to have been early factors in causing degeneration independent of the pericarditis, which operated in a purely mechanical manner to produce the fatty change. This case is another instance of fatty degeneration in the third stage.

If, then, we realize that this affection of the cardiac wall is incidental to the infective diseases, continued fevers, septic or suppurative processes, toxemias, dyscrasias, hypertrophies and atrophies, we should be on our guard to protect the patient against the inherent damage to the heart resulting from these several conditions. So we should hope either to prevent a break down of the cardiac walls, or certainly to postpone it. In infants or young children convalescing from eruptive or continued fevers, we should watch carefully their "weak hearts," and with them rest in bed and minute doses of iron and strychnine, perhaps in conjunction with some malt preparation and cod-liver oil or quinine, will usually be sufficient in uncomplicated cases, provided the diet is carefully regulated, and hurried movements, straining of muscles and nervous excitements are avoided.

In young people, such, for example, as are anemic or tuberculous, gymnastic exercises are appropriate for the intermediate stage, provided they are given under suitable medical direction and are not carried to the extreme that is customary at the present day in gymnasiums and outdoor sports. There are plenty of schools for physical instruction under medical supervision, where those convalescing from illness with weak heart-action can be greatly improved. On the other hand, we cannot too strongly condemn the class exercises of the day, if the patient has heart-weakness or in fact any form of heart-disease. Class work calls for uniform movements, usually rapid, giving few intermissions for breathing, so that it is suited only for those whose hearts are sound.

In fact, every case of weak heart should be treated by itself, whether in the young or old, and the exercises should never be carried to the point of increasing the rapidity of the heart's action beyond its normal range, which of course differs with each individual, for although we have adopted an artificial standard for the rapidity of the pulse, one man's normal pulse may be 60 or perhaps less and another's 100 or more, in some instances. Systematic exercise of a specially-prescribed variety should be insisted on, because habits of indolence tend to a fat heart, and will increase the difficulty. In fact, oily matter of any kind should be consumed by muscle work. At the same time, patients should be put on a specially-restricted diet. It prevents gaseous distention of the stomach and intestines, which provoke cardiac disturbance.

When young or old people have not the strength for voluntary gymnastic exercises, they should have resistant exercises with or without massage. These exercises are more thorough than massage, and tend to rid the muscle-cells of their granular contents, be they toxic or otherwise. But with delicate patients massage and exercises may be too severe a tax on the strength, producing too profound a reaction. The treatment should always have the effect of toning up rather than relaxing the individual. Carbonated baths, of course, are to be used in conjunction with resistant exercises in the intermediate stage of the disease; but baths and exercises are of little or any use in the third stage. And yet while they may not do any good, they may not do any harm. Massage may, however, be very grateful.

Roemer, quoted by Whittaker,[14] reports that in 234 cases of heart-weakness without valve lesions, where 81 of them were treated by the mechanico-dietetic, improved Nauheim plan, 46 recovered and 17 were improved. But neither exercises nor baths should be instituted until a careful physical examination of the patient has been made. If, for example, he is suffering from a violent attack of palpitation, rest in bed in a quiet room and a restricted diet should be ordered. Milk is excellent if it agrees with the patient. Some simple sedative like the bromide of camphor may be given, though I have often seen such patients recover from even severe attacks without any medication addressed to the heart. However, aconite in one-minim doses is sometimes useful, or a belladonna plaster may be applied beneath the breast. But if the palpitation is neurotic, such heart tonics as spartein sulphate, strophanthus, convallaria and digitalis should *not* be given. Valerian is better, and minute doses of calomel, with or without an enema, are usually soothing. In ordinary cases of fatty degenration, the patient, if he is anemic, should be put on iron; if tuberculous, on malt preparations and creosote or cod-liver oil; if atheromatous, on the iodides; if rheumatic, on antilithemic diet and remedies in conjunction with the hot-air treatment.

In the third stage, when all hope of cure by any of the above measures is at an end, and it is merely a question of prolonging life and alleviating suffering, digitalis is appropriate if there is an effusion referable to the failing action of the heart through inaction of the kidneys. In Merck's digitalis in 1/100-grain doses every few hours I have found the most satisfactory method of giving this drug. But it should not be continued more than a week or so at a time, and strychnine should follow it to maintain its effects. Other remedies that are useful in this stage are nitroglycerin, caffeine, strophanthus and spartein. Attacks of difficult breathing, if not severe, are relieved by oxygen gas, while

sudden attacks of true or false angina are best treated by the nitrites. I am apt to use a solution in these cases containing nitroglycerin, 1/100 grain; amyl nitrate, ¼ grain, menthol, 1/50 grain, and oleoresin of capsicum, 1/100 grain, all suspended in 10 minims of castor oil. A single capsule containing these ingredients I have on hand when these attacks are expected, and a single dose usually suffices. But even in the third stage it must be remembered that the degenerate heart has a most remarkable capacity for recovery, even without the so-called heart stimulants. If given their action should be constantly watched and in any case they should be used for only the briefest possible period. These remarks are especially true of digitalis, strophanthus, spartein and strychnine.

The prognosis of fatty degeneration varies with the stage, the individual and his environment, and the influence of the disease that has produced it, for fatty degeneration is not strictly a disease *sui generis*, but rather a degenerative process superinduced by a number of diseases. For example, the fatty change attendant on infective diseases or toxemias should disappear entirely, provided the heart has had rest during the stage of convalescence. On the other hand, if during convalescence the patient has been called upon to do an improper amount of physical work, dilatation may ensue and fatty degeneration in the second stage may be initiated. It is now believed by competent authorities that in infants and young children fatty change in the heart as an incident of infective diseases, or as a sequel to them, is quite common. On the other hand, a moderate amount of fatty degeneration is not inconsistent with an average life; in fact, there is a certain amount of fatty degeneration in most adult hearts otherwise sound, reflecting probably the methods of life in what we call civilized communities, where our intellectual rather than the physical parts of our system are most in use. This is well shown in the hearts of athletes. For when hypertrophy has been caused by severe training, there seems to be always a certain amount of fatty degeneration coincident with the gradual return of the heart towards its normal size, which retrograde process takes place when athletics are given up for the ordinary routine of a business or professional life. In such cases, however, when the enlarged heart fails to contract to the normal size, we may infer that the delay is owing to some other organic heart-affection, such as valvular disease or mechanical injury, as from an old strain.

In the middle point of life, when degenerative changes are the rule, a weak heart may be toned up and restored to a fair degree of soundness by appropriate treatment, though I can hardly believe a permanent cure is effected pathologically. It is one thing to restore an organ so far that it is sound physiologically, quite another to have it sound pathologically. But it is a triumph in medical art to restore the functions of the heart.

In the final stage when anasarca supervenes and the kidneys, from hyperemia or structural changes, secrete a lessened amount of urine, containing albumin and granular cells, and there is transudation of fluids into the bronchi or lungs or chylopoetic tract, interfering with the functions of these organs, the prognosis cannot be favorable. The fatal issue is certainly near at hand, and, though the heart may be sustained and the kidneys forced to do better work, it is a struggle in which Nature will eventually triumph, most likely by thrombosis, embolism, perhaps apoplexy, meningitis, or uremia.

In conclusion: Fatty degeneration of the heart is a common affection, though it is not to be classed as a disease *sui generis*, but rather as a metamorphosis or process attending on loss of compensation in valvular diseases, but also nearly as often on non-valvular diseases.

It is caused by fevers, toxemia, dyscrasias, disorders of nutrition, and mechanical injuries, but it may also be a physiological process as, for example, in senility or after parturition.

For practical purposes, it may be divided into three stages, the first or early; the second or intermediate, and the third or final, and each stage is capable of being distinguished by certain clinical signs.

In the early stage the prognosis is best for complete recovery, that is, if the patient does not yield to the primary disease, for in that case he will probably recover with a sound heart, provided of cause the heart complication is properly treated.

In the intermediate stage the prognosis is not good for the arrest of the fatty process *in toto*, but the functions of the heart may be so improved that the patient should be able to resume his former work and enjoy a fair degree of health for an indefinite period. In fact, we may expect a physiological if not a pathological cure.

In the third or final stage, which is marked by such profound implication of the internal viscera that their functions are in abeyance, the prognosis is always unfavorable. The end will rarely be delayed beyond a few months.

Horseflesh as Food.—Health board inspectors have recently found that there is quite a demand for horseflesh among the poorer classes of the East Side. A butcher of Carmine street was found to have 600 pounds of it in his store. He says that for more than six weeks he has been selling horsemeat steaks and that his customers have made no complaints but on the contrary are pleased to get meat at the low price at which horsemeat is sold.

A CASE OF PUERPERAL SEPSIS FROM RETAINED LOCHIA (LOCHIOMETRA) WITH REMARKS.

By GEORGE P. SHEARS, M D.,
OF NEW YORK;
ASSISTANT ATTENDING PHYSICIAN TO THE MOTHERS' AND BABIES' HOSPITAL; CLINICAL INSTRUCTOR IN OBSTETRICS AT CORNELL UNIVERSITY.

On July 24, 1900, Mrs. A. B., primipara, outpatient of the Mothers' and Babies' Hospital, was delivered of a male child after a labor presenting no unusual features. Except for a marked scantiness of the lochial discharge, the puerperium was uneventful until the sixth day when the patient suddenly developed a temperature of 103° F. and a pulse of 120. On the morning of the seventh day she was seen by a member of the house-staff and received an intra-uterine douche. At about 8 p. m. of the same day when first seen by the writer her temperature was 102.6° F. and her pulse 120. On vaginal examination it was found difficult to explore the intra-uterine interior, owing to the exaggerated anteflexion of the uterus, but traction upon the anterior cervical lip combined with suprapubic pressure sufficed to restore the uterus to its normal position and digital examination showed no remains of placenta or membrane. The uterine cavity was again irrigated. On the following day the patient's temperature was 98.6° F. and her pulse 104; on the next day the temperature was 99° F. and the pulse 78. There was no further intra-uterine treatment and her subsequent convalescence was uninterrupted.

This case is not reported because of its rarity, for such cases are by no means uncommon, but the fact that English and American text-books ignore the subject altogether seems a sufficient warrant for reporting it and for drawing certain general conclusions with reference to the etiology, diagnosis and treatment of puerperal infection. The prevention of infection is the supreme duty of the accoucheur the most important part of the management of normal labor. This is now generally recognized, though the means employed for the attainment of this end are often faulty. But the obvious corollary that, since puerperal infection is ordinary wound infection, the different kinds of infection should be carefully classified for purposes of intelligent diagnosis and treatment is very commonly overlooked.

In the eyes of those who still treat puerperal infection from the standpoint of the last decade, the problem is a simple one and its solution equally simple. The uterus is scraped with the curette. The results are justified by the following statistical fallacy. Many cases, of course, recover and would recover under any treatment. These are set down as successes. Some cases do not recover or are made worse, and here the infection was too virulent or the curette was not used early enough. By this kind of reasoning in a circle, the utter neglect of scientific study of puerperal infection is made convenient and easy. Time and space forbid a general discussion of the subject of curettage in puerperal sepsis. The modern standpoint has been sufficiently presented by Ohlshausen and Veit, Ahlfeld, Bumm, Whitridge Williams, and many others who have amply demonstrated its uselessness in many cases, and its danger in others, but as is usually the case with methods of treatment which have become popular, its practice will long outlast the demonstration of the fallacy involved.

It is such an easy solution of the question Puerperal infection is regarded as a kind of morbid entity localized within the uterine cavity and removable by mechanical means, and so sepsis localized in vagina or cervix, sapremia from retained lochia, streptococcus infiltration of the uterine wall, fever due to infected thrombi in distant regions, and general lymphatic septicemia, are all treated in the same way.

The prompt success of proper treatment in the condition under consideration adds another restriction to the routine use of the curette. Although intra-uterine irrigation was used as an additional precaution it is quite probable that reposition of the uterus with an ice-bag over the fundus would have been sufficient. Several recent text-books state that every case of puerperal infection should be treated by early curettage, and in at least one well-known maternity hospital, not long ago, every febrile case was curetted as the first measure of treatment. Curettage for the removal of retained lochia would be ludicrous if it were not dangerous, but that it has many times been practised cannot be doubted in view of the above advice and practice. So much for the bearing of this case upon the general subject of the treatment of puerperal infection.

A word with reference to diagnosis. The sensation communicated to the palpating finger in these cases is a peculiar one. The uterus has a boggy semi-elastic feel, which has been compared to that of the pregnant uterus. This was especially noticeable in the case referred to, and is, as the writer believes, characteristic of this variety of infection.

In this connection it is well to note that the description commonly given of the physical signs of puerperal septic endometritis often serves to lead the student astray. What are the physical signs of an endometritis due to a sapremic or streptococcic infection, a putrid or septic puerperal endometritis? In the text-books this question is answered as follows: "The uterus is enlarged, sensitive to pressure, has a boggy feel, etc." One cannot resist the conclusion that some writers have written from an academic rather than a practical standpoint, that they have pictured septic endometritis, not as by careful examination they have found it to be, but as reasoning from analogy they have thought it ought to be. In a careful and painstaking examination of a considerable number of cases of fever after delivery, the writer failed as a rule to find the above signs, and further observation has furnished him with ample confirmation of the statement of Ohlshausen and Veit that without bacteriological examination there is no positive diagnostic sign, except in those cases in which

a history of retained placenta establishes the diagnosis of putrid (sapremic) endometritis.

It is probable that in most cases, if one is familiar with the various types of infection, the diagnosis can be made with a reasonable degree of safety by a process of exclusion. But the physical signs mentioned in the text-books are in the majority of cases absent or ill-defined. They are the symptoms of diffuse metritis not of endometritis. The general recognition of this fact by the text-books would do a vast deal of good. It is the failure to find these signs which leads to the non-recognition of sepsis, which furnishes excuse for carelessness in the management of labor and in operative technic, and gives plausible ground for the diagnosis of influenza, malaria, etc., so often gravely made by men who ought to know better.

In sepsis from retained lochia, however, we do find an enlarged uterus, the enlargement disappearing with the cause. The possible, though rare, occurrence of this form of sepsis from retroflexion of the puerperal uterus should not be forgotten.

The patient's temperature, as already stated, was 103° F. In discussing the differential diagnosis between sapremic and true septic infection, most text-books lay stress upon the higher temperature-range of the latter. That this test is not always to be relied upon must have been forced upon the observation of every careful observer. That lochiometra may be, and frequently is, accompanied by a temperature of 103° F. or more, cannot be doubted. The pulse is a better criterion. A continuously rapid pulse is indicative of true septic infection. But even this sign may fail for the first day or two, the slow pulse of the puerperium persisting, and the pulse may be temporarily rapid from fright and nervousness on the part of the patient. That high temperature and pulse-rate are temporarily much exaggerated by the reflex influence of sudden uterine distention is well known.

Bacteriological examination is the final test, but is, of course, unreliable unless made by an expert and with every care to avoid contamination of the specimen by vaginal or cervical secretions. Moreover, bacteriological examination, while highly desirable from a scientific standpoint, does not always subserve the interests of the patient. All careful observers have noticed the occurrence of extension of infection as the result of curettage, and even of the intra-uterine douche. This extension is the result either of the production of abrasions which constitute new avenues of infection, or of the breaking-down of Nature's leucocytic barrier by which, ordinarily, the progress of infection is prevented. Now, common sense would indicate that to distend the vagina with a speculum, transfix and draw down the cervix, scrub its canal and then explore the cavity of the uterus is a procedure not to be undertaken unless there is a prospect of some compensatory benefit to the patient. That this is true has been shown by the recent experience of Franz (*Beiträge zur Geburtshülfe und Gynaekologie,* 1900, Hft. 3), who found that in a large proportion of cases the procedure was followed by a rise of temperature, this being especially noticeable in the cases in which the streptococcus was present. Although his examinations were conducted with the most scrupulous care, he was led to discontinue them out of regard for the interests of his patients. Thomen has also noted the occurrence of a chill and fever after bacteriological examination.

A careful study, then, of other diagnostic signs is important since it is evident that bacteriological examination should be restricted to those cases in which it is necessary for purposes of treatment that the diagnosis be made with absolute certainty; and, as the consensus of modern experience and authority is strongly against active local treatment in true septic (pyogenic) endometritis, it is evident that these cases will be exceptional, unless time proves the efficacy of the serum treatment.

It is often assumed that the mere presence of the streptococcus is evidence of the extension of infection beyond the endometrium, but this is plainly incorrect. This organism is present not only in severe cases, but in all grades of mild cases. Perhaps the last authoritative word upon this subject is that of Kroenig and Menge in their report to the Paris Congress. They conclude that, while of all the offending organisms the streptococcus has the greatest tendency to migrate from the original focus of infection, in the majority of cases, even when the streptococcus is present, the infection remains confined to the endometrium, the process being one of intoxication rather than infection.

The ordinary type of puerperal sepsis, then, is not a general nor even an extra-uterine infection, but an endometritis, septic or putrid, and its extension beyond the endometrium is to be determined by clinical rather than bacteriological data. To wait until the bacteria are found in the blood-current, as has actually been suggested, is to wait too long.

The symptoms of lochiometra usually develop rather late in the puerperium, perhaps at the end of the first week. This is the period at which the signs of uterine and para-uterine phlebitis are noticed. In both cases the uterine interior is smooth. The disastrous results of curettage and even of intra-uterine douching in these cases of phlebitis have been noted in many cases which have been reported and in many more which should have been reported.

With reference to etiology of these cases, the question remains to be answered, How do the bacteria gain access to the genital canal? This question is too often ignored altogether. Anteflexion of the puerperal uterus, with consequent lochial retention can be regarded only as a predisposing cause. We often read of decomposing lochia, but the dictum of science is positive. Neither lochial fluid nor other organic substance can undergo spontaneous decomposition. Here, as elsewhere, we must try to account for the presence of the offending organisms. Infection may, of course, be transmitted in the usual way,

i. e., by the examining finger, instruments, etc., but since all air contains saprophytes it seems reasonable to suppose that decomposition of clots and other débris may be the result of the admission of air to the vagina and uterus, especially during manipulations in the third stage of labor. This position was taken by the writer in a previous article (*N. Y. Medical Record*, Sept. 17, 1898).

According to Franz the anaerobic saprophytes of the vagina may under certain conditions find their way into the uterine cavity, causing fever of a mild type (*Eintagsfieber*) even in patients who have not been subjected to digital internal manipulations. But the nature of these organisms is by no means well understood, nor has their infectious character been proven, and, moreover, from what we know of Nature's conservative processes in normal pregnancy and labor, the idea of an infectious property in physiological maternal secretions is *a priori* improbable.

Then, too, we must be prepared to answer the question, Why do the germs become active? For it is a fact too often forgotten that the microorganisms of infection, with perhaps the exception of the gonococcus, do not by their mere presence cause fever. If they did it would be far more common than it is. This fact, well known to laboratory workers, is clinically confirmed by the fact that cases treated with no precautions whatever sometimes do well. Saprophytes and pyógenic germs may be present in the vagina and even in the uterine cavity without harm to the patient. Predisposing causes must be present and among these we recognize obstruction to the outflow of the lochia. A consideration of other predisposing causes, *e.g.*, placental retention, frequent vaginal examinations with the traumatism involved, operative procedures, delayed labor, *etc.*, would carry us too far. But the lesson to be learned can be briefly and clearly stated—while the rigorous employment of every method for the exclusion of bacteria is of the first importance, no method of prophylaxis or treatment can be regarded as even approximately correct which does not include a careful study of the predisposing as well as the primary causes of infection.

Superficially considered, there is nothing very striking or dramatic in the study of the various types of puerperal sepsis. It appeals to the thinking man rather than to the mechanical genius. There is more good to be gained by it, however, than by following the migrations of the wandering kidney or suggesting new methods of dividing the symphysis. These things have their place, but it is by the every-day study of every-day topics that we can do the greatest good to the greatest number. And this is the object of our art.

It is a striking anomaly that in obstetrics, the only branch of medical science in which the physician has to deal with two lives instead of one and in which intelligent intervention can do more good than in any other, ancient maxims and stereotyped rules are religiously followed and handed down from one generation to another.

A single familiar case like the one described presents much food for reflection, illustrating, as it unquestionably does, the fact that old errors in the etiology, diagnosis and treatment of puerperal sepsis still hold sway. The remedy is to be found in a judicious questioning of authority and in the detailed and critical study of individual cases. In seeking to clothe a neglected subject with the mantle of true science, we can not do better than to follow the advice of the poet:

"Willst du in's Unendliche schreiten
Geh' nur im Endlichen nach allen Seiten."

MEDICAL AND SOCIOLOGICAL ASPECTS OF THE GALVESTON STORM.

By H. A. WEST, M.D.,
OF GALVESTON, TEXAS.

The terrible West India hurricane which on September 8th devastated the Island and City of Galveston, as well as the adjacent country for many miles inland, has been described by able writers from all parts of the country. The manifold and heartrending details of the almost unprecedented destruction of life and property have been pictured by the pen and camera of many eye-witnesses, but as the medical and sociological features presenting series of important and interesting facts have thus far not been placed upon record I have taken this task upon myself, and without attempting any exhaustive treatment of the subject I will mention those incidents especially interesting to medical men, and draw such conclusions from them as appear to me to be warrantable. The conditions prevailing subsequent to the storm may be briefly stated as follows:

The appalling loss of life variously estimated as from one-seventh to one-sixth of the entire population amounting to six or seven thousand persons was due to a combination of causes, the chief of which was the failure to recognize the gravity of the situation until it was too late by those who lived in the vicinity of the beach front. Unquestionably many could have been saved had they sought refuge in the less exposed quarters of the city, but the false sense of security, the terrific rapidity of the engulfment and the unprecedented velocity of the wind conspired to swell the mortality to enormous proportions. The immediate cause of death in most instances was drowning. Some were crushed by falling timbers, some imprisoned beneath debris, some killed by flying slate, some knocked from floating rafts and either killed outright or so disabled as to be at the mercy of the raging waters. Sections of railroad track with heavy timbers attached swept with irresistible force, and cutting a wide swath destroyed many.

The doctrine of the survival of the fittest found here an illustration. More women and children were drowned than men, partly for the reason that proportionally more of the latter were enabled by mere physical superiority to buffet with the wind and waters and save their lives, and partly by the

fact that many men engaged in business were unable to reach their homes in the outskirts, and were thus compelled to remain in safer quarters. Out of some two hundred bodies found upon the mainland shore of Bolivar peninsula about 85 per cent. were women and children. Doubtless the same proportion occurred with corpses found elsewhere. The proportion of the injured to those killed was comparatively small, and the wounds, chiefly contused and incised, were in the main of a minor character, most of all the wounds became infected. There were a few fractures of the skull, the jaw and upper and lower extremities. The probable explanation of this fact (*i. e.*, the general insignificance of the wounds) is that those who were badly wounded were unable to save themselves by clinging to rafts or by swimming and consequently were drowned. Most of the bodies found were either entirely nude or with a small remnant of clothing. Of those who were saved many were entirely stripped of clothing, illustrating the extraordinary force of wind and water.

Some remarkable instances of self-preservation were recorded, men or good sized boys being carried to sea clinging to pieces of wreckage and floating for hours, at length by the mercy of the waves, landed upon the shore of some bayou fifteen or twenty miles from the point of departure. In no case, however, was a person of the female sex thus saved. The following incident is of interest. A house at Bolivar Point in which six soldiers had taken refuge was crushed to fragments; one of the number caught a door as it was broken from its hinges; clinging to this frail raft he floated for twenty-four hours, and drifting with the tide was finally washed ashore forty miles distant; he was the sole survivor of the occupants. If all the horrors of that dreadful night could be depicted, a tale would be told which would far exceed anything from the pages of fiction. Many heroic deeds, where lives were sacrificed in the effort to save others were performed and the heroes remain unknown, unhonored and unsung.

A notable instance of life saving which came to my knowledge should not go unrecorded. A cotton screwman named Martin Smith, although a cripple, at the risk of his own life rescued by means of a little boat over forty women and children. In addition a number of men who by holding to the boat were enabled to reach places of safety.

There is, however, a darker side to this picture. Like the foul beasts and birds of prey, who sniff the carrion from afar, hardly had the water subsided before the human hyenas and vultures commenced their nefarious work, mutilating and robbing the dead, breaking open trunks and pilfering the contents, they lined the storm stricken area and systematically stole everything they could lay their hands on. This horde of thieves gathered from every section, they flocked here from the neighboring country. The police authorities were apparently paralyzed and afforded no protection and for three days, until the city was placed under quasi martial law by the State's authorities, these robbers of the dead and unfortunate pursued their infamous occupation unmolested. Thus everywhere the sheep and goats are intermingled. There is a class in every community whose evil instincts are only held in check by the heavy hand of the law. When the opportunity for escaping punishment is presented they are waiting to embrace it, and there is no crime in the calendar they are not ready to commit. The storm was barely over before the better class of citizens organized themselves for the purpose of relief and rehabilitation. These efforts nobly and ably performed were seconded and made possible by the whole souled generosity of the outside world.

An interesting feature of the relief work was its evil effect in stimulating idleness, rapacity and greed. The gratuitous distribution of food and clothing was hardly commenced before it was found to be necessary to take stringent measures to obviate fraud. Repeaters, *i. e.*, those who would go from one ward commissary to another, and thus secure as large an amount of food as possible, were found to be numerous. A large number of idle and vicious persons were perfectly content with the prospect of free food and clothing to quit work and live a life of ease. This fact together with the increased rate of wages and ample employment of laboring men has made it extremely difficult to obtain female help. If the sociological question is ever propounded as to what influence a West India hurricane may have upon the wages of colored cooks, the answer will be easy in Galveston.

To attend to the wants of those sick and injured, temporary hospitals and dispensaries were organized in various parts of the city. Local physicians, assisted by volunteers from abroad, labored diligently and without reward for the benefit of suffering humanity. Many of them devoted their entire time to this work, although their losses were as great as that of any other class. They neither expected nor obtained any remuneration. The fact that some of our profession might be in pecuniary need seems only to have been remembered in one instance. Dr. W. R. Thompson representing the Washington (Pa.) Medical Society sent through Dr. J. R. Stuart, of Houston, fifty dollars, this money was given by me to two young physicians who needed and deserved it.

Coming to a brief consideration of the effects of the storm upon the public health, popular apprehension existed that serious disease would occur resultant from certain abnormal conditions induced by the storm. Let us enquire what such conditions were, their effects and modus operandi.

1st. *Overcrowding.*—About four thousand houses were totally destroyed, it is safe to estimate that at least two thousand more were rendered uninhabitable, upon a basis of four persons to each house, we have twenty thousand less six thousand drowned, leaving fourteen thousand people who were compelled to seek refuge and overcrowd the houses left habitable.

2d. *Filth and General Impairment of Sanitation.*—The elements composing this division are so many it is difficult to enumerate them all. Mentioning only the most important ones, we have (a) the intermingling of the contents of thousands of surface water closets and their deposit in the streets, yards, lots and houses; (b) decomposing bodies of man and lower animals by the hundred, festering beneath the debris for weeks exposed to the rays of a tropical sun; (c) decomposition of an immense amount of other organic material, such as food material of all descriptions. Many carloads of rotting grain made the air redolent. (d) The deposit of silt, two or three inches thick, composed largely of decomposing organic material was universal. In spite of a burning sun and dry weather this deposit retained its moisture. (e) Impairment of drainage. This item has been a very serious one. Always a difficult problem to solve here, now the impediments have increased a thousand fold. Holes and irregularities upon lots, streets, and alleys, destruction of grades and filling of drains, cause the water to stand even after a slight rain until it disappears by evaporation or sinks into the soil. This stagnant water is largely intermixed with rotten wood and other organic material. (f) Impaired water closet facilities. As a result of overcrowding, fecal matter was deposited upon floors, in alleys, upon lots and in the streets. Some public buildings, as the court house, where hundreds had taken refuge, were soon in a fearful condition.

3d. *Excessively High Temperature.*—The following data from the U. S. Weather Bureau is self-explanatory and was kindly furnished by Dr. I. M. Cline, Chief of the Bureau at Galveston. Every day since the storm, until September 30th has shown abnormal high ranges of temperature, varying from 3° to 8° F. The average daily excess for the twenty days was 6½° F. The lowest record was in the 17th, 83° F. The highest on the 16th, 87° F. That this excessive atmospheric heat was contributory with other factors in the development of sickness goes without saying. It is important to note in this connection that from September 30th to November 23d the same abnormal heat prevailed, with one or two exceptions.

4th. Resulting from these and other sources of uncleanliness there was an enormous increase of disease bearing insects, especially flies. Mosquitoes we have with us most always. What part they played in the development of disease will be discussed later. But, oh the flies! Never to the writer's knowledge has the Egyptian plague of flies been so fearful, they literally swarmed everywhere. The atmosphere was almost thick with them. In the butchers' pens and stalls the meat was covered with them, they swarmed upon food in the kitchens and dining rooms and constituted living witnesses of the all pervasive filth and insanitation.

5th. *The Water Supply.*—The city is furnished with water chiefly from artesian wells located twenty miles distant upon the mainland. This is piped across the bay. To a limited extent above ground cisterns or tanks are still in use. The main conduit and stand pipe was fortunately uninjured but the pumping station was destroyed. A water famine was imminent, but fortunately was averted by the wisdom and energy of Mr. McMasters, a member of the board of water commissioners, who immediately organized a large force and worked night and day until the damage was repaired and the water was flowing. For three days, the only source of supply was the tanks and a few underground cisterns, all containing water more or less impure. It was six days before artesian water was plentiful. Is it necessary to proceed further with this enumeration? Surely the conditions were sufficient to warrant the popular fear of sickness. It did not require any expert sanitarian to predict the character of disease likely to prevail, for unfortunately similar conditions have occurred from time immemorial.

Like causes produce like effects. Punishment in the shape of disease and death is sure to follow the violation of sanitary laws. Such radical departures, however, from the customary hygienic status so suddenly produced, as in the case under consideration, must be of rare occurrence. The sequence of events, the manifestations and modus operandi constitute the most interesting and practical portion of our enquiry.

I shall not attempt to give the experience of other Galveston physicians to any extent, taking it for granted that my own practice will afford a fair index as to the general situation. The first cases of sickness coming under my observation after the storm appeared to be a mild form of malarial fever. It should be mentioned in this connection that the mosquitoes disappeared entirely for at least a week after the storm. No blood examinations were made, but the clinical events and the therapeutic test pointed to malaria. It should be mentioned, moreover, that in spite of the fact that Galveston is one of the worst mosquito infested places in the world at most all seasons of the year, yet malarial diseases have not heretofore originated in this locality except to a very limited extent, while in our neighboring towns of Beaumont, Alvin and Houston, mosquitoes are far less numerous, but malaria much more prevalent. This fact was forcibly brought to my attention recently when I was called to Alvin to attend a case of pernicious paludal fever. Mosquitoes were so scarce that a bar was not required yet pernicious forms of malarial fever were prevalent. There has been, however, a very notable increase of malarial diseases in Galveston since the storm. The following from the records of the Sealy Hospital exemplifies this fact to a more marked degree than the experience of private practice. In August there were twenty-two cases of malarial fever admitted, in September also twenty-two, while in October there were seventy. Most of these were of the tertian form, a small proportion estivo-autumnal and pernicious. While a certain number of these cases were from the adjoining country, a large proportion originated in Gal-

veston. Dr. J. B. Massie informs me in regard to our neighboring city of Houston that there has been no unusual prevalence of intestinal diseases, but that malaria has been more prevalent than for many years past and that many deaths have occurred from pernicious forms; a thing rarely reported in previous years.

Whether the difference in regard to the prevalence of malaria in contiguous places is to be explained by the comparative absence of the Anopheles in one locality and their increased presence in others remains to be demonstrated. In my opinion further investigation will show other sources of malarial infection besides mosquito bites and other explanations of the facts mentioned.

The second form of sickness developed was gastro-intestinal catarrh and dysentery. The disposition to these troubles commenced a week or ten days after the storm and was very generally prevalent. A large proportion of the population were affected. Those who came to the city some weeks after the storm were taken with the same malady. In many instances the type was mild, after some nausea, coated tongue, vomiting and diarrhea, recovery ensued with little or no treatment. In a number of cases there were frequent recurrences. Severer forms of diarrhea and dysentery also were prevalent, the latter often proving rebellious to treatment and tending to chronicity. A number of cases in the hospital were of the amebic form. Children as well as adults and both sexes were alike affected. Enquiry failed in most instances to reveal dietetic errors. The drinking water was chiefly artesian, a week after the storm, and was doubtless infected.

The third form of disease to show itself was typhoid fever. My first case came under observation November 1st and is now convalescent, since then six others have come under my care, three in the city and three on the mainland in the storm stricken area. Other physicians make a similar report. The following from the Sealy Hospital records shows the rapid development of typhoid fever. Commencing October 30th, since that date until November 22d, eight cases and two suspects were admitted. Previously during October and September there were no cases.

Scarlet fever, diphtheria, epidemic influenza and dengue. I classify these infections together for the reason that although reported to be present, neither of them are thus far epidemic. In my own practice I have seen two cases each of scarlatina and diphtheria but no positive case of dengue. That the unhygienic condition of the city is favorable for the further spread of these diseases goes without saying. What the future developments may be, remains to be seen, and will depend upon weather conditions and the adoption of vigorous prophylactic measures.

Cases of Mixed Infection—There has been a very curious intermingling of various morbid processes in households, as well as individuals *e. g.*, in one house there were first several mild cases of gastro-intestinal catarrh, then a severe case of dysentery, then two cases of fever apparently malarial. Then again a person would be attacked with severe gastro-intestinal disturbance, nausea, vomiting, diarrhea, prostration, followed by rigors and intense fever. The beneficial effects of quinine in such cases would seem to indicate their malarial origin. In several instances during the progress of a regular typhoid attack such clinical phenomena as repeated rigors, excessively high temperatures, thickly coated tongue with dentated edges, were indications of malarial complications, which appear to have been demonstrated by their disappearance after thorough cinchonism. Still again the following clinical sequences were noted: Choleraic diarrhea, comatose, malarial paroxysms, albuminuria and pneumonia, recovery ensuing under heroic hypodermatic injections of quinine. The last case was at Alvin, a point twenty-five miles from Galveston, where the conditions subsequent to the storm were similar. It would be interesting to ascertain health conditions in various parts of the State and the prevailing types of sickness in comparison with conditions at Galveston. But being beyond the scope of the present inquiry the ignorance in the management of public medical affairs in this State, and the want of a State Board of Health, would render the task of an analytical study of the subject difficult and laborious.

Coming now to a brief consideration of the modus operandi of the above described conditions and results. The extensive prevalence of gastro-intestinal disorders and typhoid fever indicates the invasion of the food and water supply as well as the atmosphere with pathogenic micro-organisms. The first medium of infection was no doubt the drinking water, although the source of supply is mainly from artesian wells, the water from which is unquestionably pure when it leaves the wells, but which might have become infected in the receiving-tank. For three days, however, this supply was completely cut off and the population depended on cisterns, all of which had been contaminated by intermixture with infected salt spray and the washings from unclean roofs. While the artesian water was turned on at the end of 64 hours the provision was limited until Friday, September 14th. Even after this date many persons continued to use cistern water. Dietetic errors, imperfect cooking and the more or less continued use of canned meats and vegetables was responsible to some degree for gastro-intestinal involvement. The *flies*, however, in my opinion, became the most important media of infection when they became so numerous and so difficult to exclude, swarming everywhere and lighting upon the food from the butchers' pens to the dining table in spite of screens and every effort to exclude them; it is easy to understand how they became bearers of pathogenic germs. That the atmosphere was the medium of infection to a certain extent is also clear to my mind. In numerous instances coming under my observation, persons exposed to the emanations from decomposing bodies and other organic matter were

immediately taken with nausea, vomiting and purging. In other instances houses containing closets connected with overflowing cesspools were contaminated with foul gases. In one such house all members of a large family were sick, some with gastro-intestinal catarrh, one with severe dysentery, others with chills and fever apparently malarial. In another case a man sharing a miserable hut with his horse and cows and breathing the same emanations was the subject of a severe malarial attack. It should be mentioned in this connection that the city is practically without sewerage. There is a private plant, operating in the business districts, which has been condemned by every sanitary engineer who has examined it, which has been foisted upon the city by the verdict of a board of arbitration. Until a modern and more comprehensive system of sewers shall be secured and some adequate method of drainage be adopted, the continued prevalence of typhoid and malarial fever, as well as kindred diseases may be expected. Any scheme of rehabilitation which fails to provide for these great factors in the conservation of the public health will be fundamentally and fatally defective. It is certainly the duty of those best acquainted with these facts to call attention to them in plain and unmistakable language.

CLINICAL MEMORANDUM.

INFANTILISM.

By W. T. ENGLISH, M.D.,
OF PITTSBURGH, PA.

The case represented by the photograph is that of a child, aged seven years. Her growth has been retarded and she has a much younger appearance. The mother tells me that at birth this child weighed ten pounds and she grew in size until after the expiration of the first year. At an indefinite period in the second year, growth and development were suspended; no physical or intellectual advance was observed, until about eight months ago, when she was brought to me for diagnosis and treatment, November 24th last.

The father and mother are Americans by birth, free from personal physical blemish and of negative heredity. Two other children, older, have always enjoyed excellent health. The weight of this child when first seen by me was twenty-seven and one-half pounds, and she measured just thirty-two inches in length. The general health was mediocre, the tongue furred, the bowels irregular and inclined to constipation. The urine was normal in quantity and repeated analyses did not betray anything unusual. Pulse-rate 100 to 110, respiration 28, temperature normal. Color was pale and anemic. The skin and subcutaneous tissues were infiltrated and were thick and clumsy, to both sight and touch. The cheeks were chubby, the eyelids swollen, nose broad and flattened, the mouth inclined to remain open, the lips thick and pouting. Cushion-like rolls about the neck, axillæ, abdomen and lower extremities, betraying the general dermal infiltration, were objectified in the profile view. The abdominal protuberance, exaggerated buttocks, the massive thighs appeared in contrast with the pallor and the general aspect of disease. The hair was long and of poor quality and was falling out. The teeth were illy formed and snag-like. The nails were dry. The fontanelles were persistent.

More noticeable than these obvious signs of bodily lack of growth were those betraying mental torpor. The child was carried in the mother's arms. She was unable to walk or even to stand unaided, but fell resistless to the side toward which the body inclined. The face was dull and apathetic. Muscular movements of the extremities were sluggish, because of mental dulness rather than local swellings. Mental and muscular energy were wanting. Speech, if attempted, was not intelligible and resembled the echolalia of the feeble-minded.

Diagnosis may be casually made in similar cases, by signs rather than by careful inquiry after symptoms. This is a plain case of infantilism or myxedematous retardation. Myxedema is generally admitted to be a symptom or combinations of symptoms of inherent or acquired deficiency or disease of the thyroid gland. That infantilism is invariably due to thyroid inadequacy is well established. While much is unknown of the morbid anatomy of myxedema, the principal lesion is laid to the charge of the thyroid.

The treatment has been by thyroid extract. The tablets used were of five grains each. These were divided and one-half tablet administered in broth or bouillon night and morning. Gradually increased, the dosage has reached fifteen grains each day. This amount will be continued for some time.

Thyroid treatment, in cases long neglected, may remove the myxedematous symptoms, but has little or no effect upon the cachexia. This emphasizes the importance of beginning treatment at the earliest possible moment, if the hope of a complete cure is to be entertained. The treatment must be persisted in year by year and possibly continued throughout life.

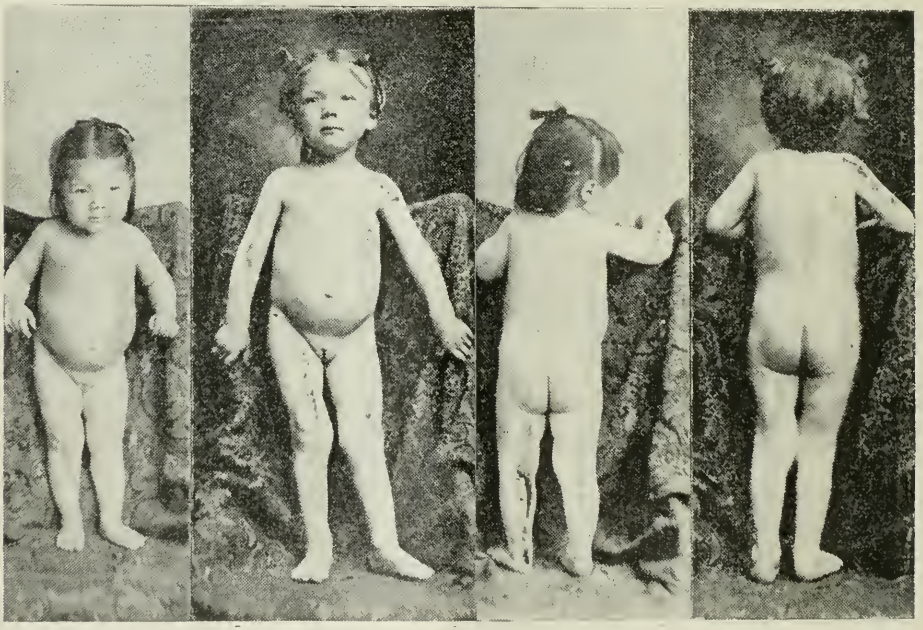
The results of treatment in this case during the eight months under my care are as follows: Weight began to diminish in a few days after the thyroid was employed and the loss of two and one-fourth pounds at the end of two months might have prompted a change but for other hopeful signs. Moreover, this temporary reduction in weight corresponded with the period of most rapid diminution of the dermal infiltration, and during this time the fontanelles closed as if by magic. This loss was recovered rapidly, so that at the end of the third month the weight was the same as at the beginning of

treatment. This ratio of increase continued throughout the fourth, fifth, and sixth months, so that six and three-fourth pounds were added. During June the growth was much slower and three-fourths pounds were accumulated. The total weight gained after recovering the two and one-half pounds lost is seven and one-half pounds; but if we add the two and one-half pounds regained, after reduction of infiltration, there is an aggregate increase of ten pounds. This extends the weight from the original twenty-seven and one-half pounds to thirty-five pounds, the present weight.

anemic pallor of the surface of the body has given way to a wholesome ruddy hue. The hair has improved in quantity and quality and the teeth and nails are assuming a normal appearance.

The changes that have come over this child during the eight months past exemplify what can be done for these cases of myxedematous retardation by the use of thyroid. Muscles and mind are restored to activity, and speech, so long denied, now mingles with song and laughter.

Although still in arrears, compared with children of her age, in mental and bodily capabilities, the prognosis is full of hope. That this child will yet attain mental and bodily vigor, equal to that of other children of the same age, is assured by every return from the treatment during the short period of eight months. Greater results will follow as the treatment continues, and at the termination of another year, few if any traces of the long drowse of mental and physical powers will be detected. At the period of maturity, if the child's health continues, and the treatment is unremitting, there will be an equality, mental and physical, with others of her age, and thus the time lost will be redeemed.



November 25, 1899. July 25, 1900. November 25, 1899. July 25, 1900.

The month of June was the month of the greatest muscular and mental activity of the child's life, and therefore a period of development rather than augmentation in size. In July she increased one inch in height, but the weight remained stationary. The length of the child was found slightly extended after the lapse of the first six weeks of treatment, but a gradual increase has persisted, giving a total of thirty-seven inches—a gain of five inches.

The pulse, respiration and temperature and general health have continued fairly constant to the normal lines. The pulse being the most vacillating, at times, without cause, accelerating and departing from the normal rhythm. The

MEDICAL PROGRESS.

Transmission of Yellow Fever.—The Army Yellow-Fever Board has recently made a very careful investigation into the causation and transmission of yellow fever and seems to have conclusively proven that the mosquito is responsible for the spread of this disease, as well as that of malaria. C. FINLAY (*Med. Rec.*, Jan. 19, 1901) reminds us that he wrote a paper in 1891 in which he advanced the theory that this disease was in all probability communicated by means of the *Culex* mosquito, since it would be difficult to explain the peculiarities in the propagation of this disease in any other way. He was, however, unable to prove his theories. The climatic and topographical conditions favoring the communication of yellow fever are: Temperature from 70° to 90° F.; atmospheric moisture with proximity to the sea and low altitudes (usually not above a few hundred feet). These same conditions are necessary for favorable development of the mosquito. Only lately the crucial test has been made by experimental inoculation. Characteristic attacks followed each of five inoculations after an incubation of three and one-half to four days.

Dyspeptic Asthma.—Nearly all authorities describe an acute form of this condition, with sudden onset after a heavy or indigestible meal and a rapid subsidence of all the alarming symptoms after the stomach is emptied of the gas or disturbing food. F. H. MURDOCK (*N. Y. Med. Jour.*, Jan. 12, 1901) has seen a number of cases which he describes as chronic dyspeptic asthma. It is characterized by severe dyspnea on slight exertion, occurring in patients suffering from gastro-intestinal troubles, without any organic lesion of the lungs, heart or kidneys, and yielding to treatment of the digestive tract. Eating does not usually increase the dyspnea, unless exercise is indulged in; vomiting seldom occurs and belching does not relieve the symptoms as it does in the acute forms. The constant appearance of shortness of breath after the slightest exertion is the chief point of interest. Severe attacks will pass off within a few minutes without the aid of medicine, and without vomiting or belching of wind, but the permanent relief of the symptoms must be sought for through the treatment of the digestive organs.

Ear-Disease.—In a very interesting paper read by W. H. THOMSON (*N. Y. Med. Jour.*, Jan. 12, 1901), on the "Importance of a Knowledge of Ear-Disease to the General Practitioner," he has very clearly demonstrated by practical examples the grave responsibility which rests upon the physician who is unable to recognize the early symptoms of serious ear-trouble and its complications. In speaking of vertigo he classifies it as follows: (1) Gastric or digestive; (2) cardiovascular; (3) ocular; (4) aural. The first may annoy the patient greatly, but he is seldom frightened. The second variety, when due to weakness of the heart, is always accompanied by nausea and is usually transient. Ocular vertigo has a purely psychical basis. It does not occur in the dark, but the eyes must be open and looking out. Its explanation is that the general muscular tonus which maintains our equilibrium has for one of its main elements the knowledge reaching the centers through the optic nerves and when the eyes suddenly find a lack of surroundings the muscular tone loses its ordinary stimuli and general muscular tremor results. Closing the eyes or fixing them upon a near-by object usually relieves the sensation. In aural vertigo, however, when the semicircular canals are involved the patient feels as if he were dropped into a bottomless pit and the employment of the muscular and visual senses are of very little benefit in giving relief. Fear is an invariable accompaniment and may outlast the vertigo. All cases of dizziness, when fear is an important symptom, or which comes on when the patient is lying down, demand a careful examination of the ears.

Treatment of Whooping Cough.—After considering briefly the etiology of this disease H. F. THOMPSON (*Phila. Med. Jour.*, Jan. 12, 1901) discusses the treatment and reports in detail five cases which he has treated recently with heroin. He finds that heroin administered in whooping-cough allays the cough and eases respiration, the number of respirations being reduced, but their force and volume of inspired air being increased. The drug was always well tolerated, and rendered the attacks much more infrequent and less violent, while there was also an improvement in the general condition of the patients. In Case I., aged twenty months, with a very severe cough accompanied by vomiting, heroin, gr. $1/48$, at intervals of four to eight hours, given for four days, brought about the complete disappearance of the cough with no unpleasant complications. Case II., aged four years, had had pertussis for four weeks. The paroxysms were very severe. Heroin, gr. $1/24$, was given every four hours for several days, with a rapid amelioration of all symptoms. Case III., an adult, took several doses of heroin at irregular intervals and was much relieved. The symptoms gradually subsided and the cough disappeared. Case IV., aged fifteen months, had had whooping-cough for three months, vomiting every day. Four doses of heroin, grain $1/24$, stopped the cough for several days. On the reappearance of the cough heroin, grain $1/24$, three times daily resulted in the prompt subsidence of all the symptoms of pertussis. Case V., an adult, took heroin, grain $1/12$—in all, six doses—for pertussis which he had had for a week, with the result that the severe retching and almost constant cough disappeared promptly and entirely.

Removal of Cataracts in the Insane.—WILLIAM CAMPBELL POSEY (*University Medical Magazine*, Dec., 1900) cites two cases in both of which loss of sight precipitated loss of mind, and

restoration of vision was attended by immediate and permanent return of normal mentality. The first patient was a man, forty-five years of age, and was said to have had cataracts which had rendered him practically blind for three years previously. His loss of vision was attributed to the grip. His father had been insane. As his vision began to deteriorate, his mind began to fail also. He became irritable, morose and greatly depressed, and thought that his wife and his friends were plotting against his life. He threatened to kill his wife and finally tried to cut his own throat. His condition was one of great depression, he was not excited, but the delusions of persecution persisted. Rest and tonic treatment did no good. Posey examined the man's eyes and found a cataract in each. Under ether the ripest cataract was removed. The bandages were removed at the end of the tenth day. A noticeable improvement in his mental condition began to be apparent as soon as he was permitted to see, even before the correcting glasses were prescribed. At the end of a month his glasses were given him and his mind was in such a condition a few weeks later that he was permitted to go home. There has been no relapse in his mental condition in over two years, and he continues to be a sober, rational and happy member of society. The second case was a woman, sixty years of age, whose sight had been failing for several years, until she was unable to read or to get around the house without difficulty. As her sight failed her mental condition changed. She became much depressed and melancholic, fearing that she was becoming hopelessly blind. An examination showed a cataract in each eye. Her mental condition became so depressed that it was almost impossible to live in the same house with her and it was decided to remove the ripest cataract. Her mental condition became markedly improved as soon as she knew the cataract was removed and that she could see clearly with that eye. At the end of six weeks she received correcting glasses. She regained her normal mental condition and there has been no relapse. Posey thinks that, while such cases are rare and all efforts may be unavailing, every means which may possibly better the condition of the blind insane should be tried.

THERAPEUTIC HINTS.

Hemorrhage in Typhoid.—Avoid all movement, writes Mitchell Bruce, even for the use of the bedpan, collecting the stools in a properly arranged towel. Reduce diet to a minimum, giving, for example, half an ounce of peptonized milk every half-hour, or a teaspoonful of meat jelly every hour. Thirst may be relieved by wetting tongue and lips, or with a teaspoonful of quite warm water, plain or acidulated; this is better than ice. A hypodermic of morphine arrests peristalsis and aids in producing sleep and mental rest. An attempt should be made to stop the bleeding by astringents, the most powerful of which is a mixture of lead acetate, morphine acetate, and diluted acetic acid in water, or lead-and-opium pill, or lead acetate suppositories; or an ice-bag may be applied to the right iliac fossa. Brandy is to be given, with the finger on the pulse, in greatly reduced dozes at very short intervals, for instance, grams 2.0 (ℳ xxx) every half-hour in a tablespoonful of milk, so that whilst the heart is never excited by the alcohol, its strength is sustained. The value of hamamelis, ergot, and turpentine is still an unsettled question.—*Treatment in Practical Medicine.*

Acute Gout.—A sufficient quantity of colchicum should be given, writes Roberts Bartholow, to increase secretion from the skin, the intestinal mucous membranes, and the kidneys, but nausea and vomiting should be avoided. Combination with an alkali increases the therapeutical effect, as:

℞ Vin. seminis. colchici..... 12.0 (℥ iij)
Spt. ammon. aromat....ad. 60.0 (℥ ij)

M. Sig.: Grams 4.0 (℥ j) q. 3 h. until some physiological effect is produced. The London Hospital formula is:

℞ Tinct. colch. sem..... 1.3 (ℳ xx)
Potass. bicarb..... 0.7 (gr. x)
Aq. pimentæ.....ad. 30.0 (℥ j)

for one dose. After the more acute symptoms have subsided the following of Sir Henry Halford may be used:

℞ Ext. colch. acet..... 0.4 (gr. vj)
Pulv. ipecac et opii.....
Ext. colocynth. comp. aa. 0.8 (gr. xij)

M. Ft. pil. No. xij. One night and morning. Or the following:

Ext. colch. acet..... 0.7 (gr. x)
Pulv. digitalis.....
Ext. colocyath. camp. aa. 1.3 (gr. xx)

Ft. pil. No. xx. One two or three times a day. —*Materia Medica and Therapeutics.*

Pericarditis.—If sthenic, writes H. A. Hare, five or ten leeches may be placed over precordium, and aconite or veratrum administered. Calomel, gram 0.03 (gr. ss), every hour, with opium to prevent purgation, tends to prevent plastic exudate. An ice-bag to precordium quiets the circulation, lessens inflammation, and reduces temperature. If effusion takes place, the heart may need digitalis, caffein, or alcohol; if effusion is large, aspiration is advisable. The best place for making the puncture is in the fourth or fifth intercostal space one inch to left of sternum. Should pus be present, free drainage should be gradually established. If the patient is strong a hydrogogue purgative, such as compound jalap powder, gram 1.3 (gr. xx), elaterium, gram 0.01 (gr. $^1/_6$), or a concentrated saline may be effective. A blister over precordium is often of use.—*Practical Therapeutics.*

NEW YORK STATE MEDICAL SOCIETY.

IN his inaugural address before the New York State Medical Society at Albany this week the President drew attention to what is a grievous and outrageous bill presented to the legislators by Senator Grady, of this City. The origin of its provisions appears to be the various hospitals of the city, notably St. Vincent's and Mt. Sinai, in an organized effort to put all responsibility for malpractice upon the attending physician or surgeon and relieve the hospital of it. This means that whatever ignorance of a pupil-nurse, or whatever inexperience of a young interne, or whatever official neglect on the part of the hospital may be adduced as contributive or essential to the victim's misfortune, the final legal responsibility, in terms of money, well-deserved reputation and high professional position, shall rest with the member of the medical board attending the patient.

When one reflects upon the relation of principal and agent existing between these institutions and their attending staff, upon the fact that the medical service rendered is always the best in the power of each and never under remuneration, and upon the universal usage by which a person is admitted as the patient of the hospital and never of any given man, it seems that some one has erred by intention or accident in fancying that such a bill will be just. To defeat overwhelmingly this measure should be the purpose and endeavor of every reputable medical man and organization in this State, whether the effort be made through his own representatives in both legislative halls at Albany or through his Society or in any other way.

At this very session a wise bill will be presented providing that any one suing a physician for malpractice shall deposit a bond which shall be forfeited to the defendant if the suit fail. Hospitals might be included. At any rate, let us not brook for one instant any attempt to work such inexpressible, heinous and outrageous injustice as the bill of Senator Grady implies.

Another question officially brought by its President before the meeting of the State Medical Society is concerned with the organization of an association among the medical profession of the Atlantic Coast States similar to that which exists in the Valley of the Mississippi and Slope of the Pacific. Fully sixty per cent. of our brethren practise along the Atlantic and yet are behind the others in not uniting thus. Such a society would be a potent factor for public and professional good, would deserve the endorsement and cooperation of all first-class men and fulfil many interstate needs. Its official organ would be among the best in the country. We say, then, all hail, success and prosperity to a movement which when duly begun will deserve generously all these and more *in perpetuam*.

Judged from all points of view, scientific, social and economic, the present meeting of the New York State Medical Society was an immense success and the deliberations of this body demonstrate anew its great usefulness to the practitioners of the State.

THE PROGRESS OF MEDICAL EDUCATION IN AMERICA.

WE publish this week the first of a series of articles that will appear from time to time in the MEDICAL NEWS on the medical colleges of the United States.

In contrast to the three medical schools that existed at the beginning of the nineteenth century there are to-day one hundred and fifty-five in this country. Many of these are small and unpretentious institutions, but there are a large number of the first rank, and with their history is bound up the story of the progress of medicine during the century.

The increasing of the former regulation course of two years to four, the illustrating of once dry, statistical lectures with clinical material, the equipment of laboratories for the practical study of every technical branch of medicine, all are not only indications of the increasing power and prosperity of any individual college, but are significant of the vast strides that the subject of medicine has taken, and of the amount of information that every well-equipped institution has stored up for its students.

Nothing, perhaps, indicates the change in the spirit of the times so much as the business methods on which the colleges are now managed. Until within the past twenty years all the medical schools, even those connected with the large universities, were practically private corporations. The members of the faculty took all the fees, spent what money was absolutely necessary to provide what would appear now to be a very scanty and meager education, and divided the profits. But at the present day the fees are taken by a board of trustees, who pay salaries to the faculties and spend the rest upon the development of the college along the most liberal lines.

Every new acquisition to each college has signalized a broader spirit of education for the country at large, for the progress of each is an incentive to all the others. To the medical practitioner the opportunity is given in this series of articles to see, not only what his own *alma mater* has contributed to the profession, but how all have worked together, supplying knowledge, experiment and incentive to investigators and to students, and how the history of the development of the medical colleges of America is in reality the history of American Medicine.

DR. OSLER ON THE PROGRESS OF MEDICINE.

The lifting of the curse of suffering from the sin-begotten sons of Adam by the medical discoveries during the last hundred years has been the greatest gift of the century.

Dr. William Osler, M.D., F.R.S., in his fascinating review of the history of "Medicine in the Nineteenth Century," published in the New York *Sun* of Sunday, January 27th, states emphatically that, measured materially or sociologically, there is no one thing that can compare with the decrease of physical suffering in man, woman and child when stricken by disease or accident.

The greatest discovery, measured by the life-saving standard, that medicine ever witnessed occurred in the latter part of the eighteenth century, when Dr. Jenner established a means of preventing smallpox. When we remember that 2,000,000 people died in Russia in a single year of this disease, and that it was rare in Jenner's day to meet an Englishman who had not had it, we realize that the century dawned auspiciously with such a discovery.

The first steps toward further knowledge of disease, as Dr. Osler points out, were fundamental and related to a more thorough knowledge of morbid anatomy, physiology, chemistry and pathology. The careful studies by Laennec of the heart and lung and abdominal organs really laid the foundation of modern clinical medicine, and excellent work in France and America differentiated fevers, typhoid, typhus, yellow fever and the malarial group.

But the most distinguishing feature of the scientific medicine of the nineteenth century has been the phenomenal results which have followed *experimental investigation*, along lines which have determined the condition of the organs in health and the conditions under which perversions of these functions occur in disease.

Although the contribution was written for the general reader even physicians cannot help but be lost in wonder, as the vivid strokes of Dr. Osler's pen portrays one discovery after another, that so much has been done in a single century. The exploding of the "spontaneous generation" theory, and the establishing of the bacterial origin of many diseases, the laws of sanitation, and the discovery of means of contagion that have kept bubonic plague and cholera from our shores, the stamping out of smallpox and yellow fever, the blessings of anesthesia in operations and in childbirth, the discovery of antisepsis in surgery, and the lessening of mortality in childbearing, the remarkable methods of treating and caring for the insane, the decreasing number of cases of contagious diseases, and the treatment that tends to recovery, especially in diphtheria and typhoid, the establishing of hospitals and clinics, and the training of nurses, and, above all, the possibility of checking man's greatest foe, tuberculosis, all these factors of modern medicine are the result of the last fifty, many of them of the last thirty years' investigation.

We cannot but wonder how Dr. Osler's summary would read in the year 2001, and whether it would seem but the alphabet of the twentieth century's record. Certain it is that whatever the future unfolds will be the result of the investigations of the nineteenth century.

In conclusion he notes the tendency at the decline of the century to return to psychical methods of cure, in which faith in something is suggested to the patient. "After all," he says, "faith in us, faith in our drugs and methods, is the great stock in trade of the profession. In one pan of the balance put the Pharmacopœias of the world, all the editions from Dioscorides to the last edition of the United States Dispensatory; heap them on the scales as did Euripides his books in the celebrated contest in the Frogs; in the other put the simple faith with which from the days of the Pharaohs until now the children of men have swallowed the mixtures these works describe, and the bulky tomes will kick the beam."

TO EXCLUDE THE QUACK.

A new medical bill has just been introduced into the Senate of New York State which demands the attention of every practitioner in the State. After certain minor modifications it should, we believe, receive their earnest support. The text of the proposed bill is as follows. The matter in italics is new.

Section 1. Section one hundred and fifty-two of chapter six hundred and sixty-one of the laws of eighteen hundred and ninety-three, entitled "An act in relation to the public health, constituting chapter twenty-five of the general laws," is hereby amended to read as follows:

Section 152. Construction of this article. *Any person shall be regarded as practising medicine within the meaning of this act who shall prescribe, direct, recommend, or advise, for the use of any other person, any remedy or agent whatsoever, whether with or without the use of any medicine, drug, instrument or other appliance, for the treatment, relief, or cure, of any wound, fracture, or bodily injury, infirmity, physical or mental or other defect or disease.* This article shall not be construed as *prohibiting the service of any person in an emergency, or the domestic administration of family remedies; nor shall it be construed* to affect commissioned officers serving in the United States army, navy or marine hospital service, while so commissioned; or any one while actually serving on the resident medical staff of any legally incorporated hospital; or any legally registered dentist exclusively engaged in practising dentistry; or any manufacturer of artificial eyes, limbs or orthopedic instruments or trusses in fitting such instruments on persons in need thereof *when such artificial eyes, limbs or orthopedic instruments or trusses are prescribed by lawfully qualified physicians;* or any lawfully qualified physician in other States or countries meeting legally registered physicians in this State in consultation; or any physician residing on a border of a neighboring State, and duly licensed under the laws thereof to practise medicine therein, whose practice extends into this State, and who does not open an office or appoint a place to meet patients or receive calls within this State; or any physician duly registered in one county called to attend isolated cases in another county, but not residing or habitually practising therein. This article shall be construed to repeal all acts or parts of acts authorizing conferment of any degree in medicine causa honoris or ad endum or otherwise than on students duly graduated after satisfactory completion of a preliminary and medical course of not less than that required by this article, as a condition of license.

Section 2. This act shall take effect immediately.

The bill calls for little comment; its provisions are straightforward and its purposes plain. It is not special, nor class legislation; it does not seek to hinder legitimate competition; it is not meant to work hardship on any class, especially not the manufacturers of proprietary remedies, who seem to be arrayed against some of its provisions; it is simply a plea to protect the community from the quack and the charlatan.

"A law for the purpose of protecting the people from incompetent practitioners of medicine, which compels educated physicians to undergo examinations to demonstrate their ability, and which cannot be enforced against quacks and charlatans—who, because they do not use drugs, claim they are not practising medicine within the meaning of the law—certainly cannot be said to accomplish the purpose for which it was enacted." Such are the provisions of our present medical law, and it is time that a more radical and perfect instrument should be placed on our statute books.

THE LUNACY COMMISSION BILL.

THERE is one feature in the modified Lunacy Bill that calls for indignant protest. According to the first provisions of the statute it was necessary for the President of the Commission in Lunacy to be a practising physician of ten years' standing and to have had five years' special training in hospitals for the insane. As it now reads, this last clause is amended and any physician of ten years' practice is deemed a worthy candidate for the responsible position.

We believe this proposition to be preposterous, if not outrageous. There is no work connected with medicine that needs so much careful and special training as that related to the study and care of the insane person. To assume that any physician of ten years' general practice who probably does not see ten patients, in the ten years, afflicted with a mental malady is thoroughly equipped to look after the thousands of New York State's insane is to take a position that admits of little but condemnation. The inference that there are no qualified and able men is distinctly unfounded.

It is to be hoped that Governor Odell's economic utterances are not the usual virtuous platitudes of those in high office, and that in the Brackett Bill he will be as capable of spying this weak place as he is in ferreting out wasteful expenditures of the taxpayers moneys.

ECHOES AND NEWS.

NEW YORK.

Physician to County Jail.—A competitive examination for this position, paying $1,000 a year, open to residents of New York County only, will take place February 16th, 1901, in New York City.

Arsenic in American Beer.—It was stated last week at the meeting of the Society of Chemical Industry that arsenic had been found in appreciable quantities in American glucose, notwithstanding the reports to the contrary. This statement is said to have been made by Dr. A. C. Langmuir, of New York. Should this be true its presence in beer could not be gainsaid. Dr. Coblentz, of the College of Pharmacy, maintained that the Gutzeit test employed by Dr. Langmuir was not a trustworthy one to decide the question.

New York Academy of Medicine.—Order of business for stated meeting, February 7th, 1901: (I) Presentation of a bust of the late Dr. Horace Green, by Dr. D. B. St. John Roosa. (II) Papers on the Conservative Operations upon the Uterine Appendages. (*a*) On Their Technic, by Dr. Dr. J. Riddle Goffe. (*b*) On the Significance and Importance of Such Conservative Operations, by Dr. W. M. Polk. (*c*) On the Immediate and Remote Results in One Hundred Cases of These Operations, by Dr. W. L. Burrage of Boston, Mass. (*d*) An Experience in One Hundred and Twenty-five Similar Cases, by Dr. A. P. Dudley. Drs. Coe, Boldt, Wiggin, and Grandin will take part in the discussion.

Dr. Frank C. Merriam.—The Society of the Alumni of the City Hospital at their last meeting adopted the following preamble and resolutions on the death of their fellow member, Dr. Frank C. Merriam: "*Whereas,* In the death of Dr. Merriam we have lost an esteemed and valued friend, associated with us in the membership of our Society for nearly its entire existence, we desire to acknowledge the mutual friendship and helpfulness we have enjoyed from these years of association. Therefore, be it *Resolved,* That we express our sincere and heartfelt sorrow at his death, and that our deepest sympathy be tendered to his bereaved family. Further be it *Resolved,* That a copy of these resolutions be sent to the family, to the medical journals, and be entered upon the minutes of our Society. Adolph Rupp, M.D., A. T. Muzzy, Wm. L. Stowell, *Committee.*

New York State Medical Association.—A meeting of the members of the Fifth District Branch of the New York State Medical Association residing in Westchester County was held on Tuesday, January 22d, at two o'clock, at the house of Dr. N. J. Sands in Portchester, at which was organized the Westchester County Medical Association and the following officers elected: President, Dr. N. J. Sands; Vice-President, Dr. J. L. Porteous, of Yonkers; Secretary and Treasurer, Dr. Donald T. MacPhail, of Purdy Station, N. Y.

A meeting of the members of the Second District Branch of the New York State Medical Association residing in Rensselaer County was held in Troy on January 10, 1901. The Rensselaer County Medical Association was organized, by-laws adopted, and the following officers elected: President, Dr. C. S. Allen, of Rensselaer; Vice-President, Dr. M. B. Hutton, of Valley Falls; Secretary and Treasurer, Dr. F. A. Smith, of Troy.

Mount Sinai Hospital.—Work is to be begun immediately on the new Mount Sinai Hospital, which is to cover the entire block between Fifth and Madison Avenues and 100th and 101st Streets and is to cost, including the site, $1,600,000. Of this amount all but $225,000 has now been subscribed. That was the announcement made last week when the Mount Sinai Hospital Association held its annual meeting in the Hospital Training School, at No. 149 West Sixty-seventh Street. The annual report acknowledges donations to the new enterprise to the amount of $470,000. Of that sum $75,000 has been subscribed to the building fund within the last two weeks, and other individual donations of $50,000 and $20,000 respectively are now made public for the first time. There will be in all nine buildings. Their general style of architecture will be Romanesque and the material used will be brick, with stone trimmings. The executive building and wings will occupy the 100th Street side. On the 101st Street front will be the building for surgical and medical cases which will have accommodations for about 360 patients. The dispensary building and training school will be on the Madison Avenue corners, while the private hospital, perhaps the most ornate structure of all, will have the frontage in Fifth Avenue. Accommodations for the children's pavilion, kitchens, laundry, isolation and pathological buildings will be found on the 101st Street side.

PHILADELPHIA.

Philadelphia Hospital.—Plans for a new site and buildings for the insane department and a building for the treatment of skin diseases have been approved. With improvements and a complete reorganization it is destined to become one of the greatest public hospitals in the world. Thirteen additional members of the medical board have been recently elected, making in all 66 visiting physicians.

Antivivisection Society.—The annual meeting of the American Antivivisection Society was held in this city January 24th. Addresses were made by Matthew Woods, M.D., who was elected President for the ensuing year, and by others. The Secretary's report drew attention to what were declared to be abuses of vivisection at Jefferson Medical College during the past summer, certain people having been disturbed by the cries of dogs coming from a room in the College. It was claimed that the authorities of the College refused to answer letters regarding the matter. Inquiries fail to show that such letters were received.

Medical Schools and the State Medical Council.—The discussion regarding the requirements of candidates for license to practise medicine in Pennsylvania and, growing out of this, the entrance requirements of medical schools, is still in progress. A recent issue of the *Pennsylvania State Medical Journal* gives the position taken by the Council. The report that the large number of failures—42 per cent.—at the December examination of the Board was due to the raising of the literary standard was hardly correct. A member of the Council states that a large number of the 87 candidates were those who had previously failed one or more times, although the grading was perhaps a trifle more close than usual.

Hereafter a graduate in medicine who has not had four years' instruction in a medical school cannot take the examination for State license. This ruling clashes with medical schools which allow college graduates, students in dentistry, pharmacy, etc., to enter the second year. The Medical Council disclaims any attempt to discriminate against collegebred men, but wishes to see the standard of the medical profession raised, the barring of illiteracy, and the inauguration of a systemized curriculum in every medical school, such curriculum extending over four full years. It is the belief of the Council that medical schools should have such a curriculum that students must enter the first year of the course, a thorough preliminary education being needed for the comprehension of even the first year. It is stated that the only medical school in the State which has thus far adopted a systematized curriculum is the University of Pennsylvania. As a result of this only ninety-eight out of between two and three hundred candidates were accepted in the examinations of the fall of 1900.

CHICAGO.

New Editor of "Chicago Clinic."—This journal hereafter will be edited by Dr. M. P. Hatfield.

Appointment of Dr. Zapffe.—Dr. Fred C. Zapffe has been appointed Professor of Histology in the Medical Department of the University of Illinois (Chicago College of Physicians and Surgeons).

Smallpox.—The City Health Department has called attention to the fact that nearly all the persons who are suffering with smallpox at the Isolation Hospital were never vaccinated or had not been vaccinated in recent years.

Additions to the Corps of Teachers at Rush Medical College.—These are D. G. Lingle, Professor of Experimental Physiology; W. D. Zoethout, Laboratory Professor of Neurology; F. C. Waite, Assistant in Anatomy, and C. H. Miller, Technical Assistant in the Department of Anatomy.

Chicago Neurological Society.—At a meeting held January 17th, the following officers were elected: President, Dr. Hugh T. Patrick; Vice-President, Dr. L. F. Barker; Recording Secretary and Treasurer, Dr. Sydney Kuh; Corresponding Secretary, Dr. Charles H. Lodor; Member of Council, Dr. Daniel R. Brower.

Disinfection of Books.—The Board of Public Library Trustees recently adopted a resolution by Dr. W. A. Kuflewski, of providing for the appointment of a special committee to disinfect all the books on the shelves of the library. Several cases of disease have recently come under the observation of Dr. Kuflewski which convinced him that disease is spread by means of the books in the public library. Sick people are great readers and frequent the library more than any other class. The books can be disinfected at a small cost, and the public is entitled to this protection.

American Medical Missionary School.—Backed by the Battle Creek (Michigan) Sanitarium, the American Medical Missionary College in this city will erect two four-story buildings for its own use in the neighborhood of the Cook County Hospital. These buildings will house the college, hospital and afford dormitories and dining-halls for the students. The outlay contemplated is $150,000. The college has been in existence five years and was incorporated under the laws of Illinois. Dr. J. H. Kellogg is the chief physician and instructor at the college.

GENERAL.

Plague in England.—Another death from the plague has occurred among the members of the crew of the British steamer "Friary," which left Alexandria December 22d, bound for Hull, by way of Algiers.

Society of Pathologists and Bacteriologists.—An American Association of Pathologists and Bacteriologists was instituted at a meeting held in New York City January 26, 1901. The fol-

lowing officers were elected: Dr. W. T. Councilman, President; Dr. H. C. Ernst, Secretary; Dr. Eugene Hodenpyl, Treasurer. The first regular meeting of the Society will be held in Boston April 5th.

Plague in San Francisco.—Professor Frederick G. Novy, of the University of Michigan, left last week on an important mission for the United States government. He goes in all possible haste to California to investigate the likelihood that the bubonic plague, or "black death," is about to break out there, and, if such be the case, to institute every repressive measure known to medical science. It is understood that Dr. Novy is to carry on the work suddenly interrupted by Dr. Kinyoun's illness.

"Journal of Hygiene."—The first number of this new journal, to be devoted to original work in hygiene has just appeared. The senior editor, Dr. George F. Nuttall, is well known for his excellent work. The papers in this number are varied and valuable. Anopheles and the Distribution of Malaria, Pathogenic Organisms in Milk, Industrial Lead-Poisoning, Carbonic Acid in the Air, Artificial Modification of Toxins, Isolation Hospitals and Scarlet Fever. These, with other short notes, show the wide interests that the new journal will subserve. It is to be published quarterly at a price of $4.00.

American Medico-Psychological Association.—The next annual meeting of the American Medico-Psychological Association will be held in Milwaukee, Wis., June 11, 12, 13 and 14, 1901. The date has been placed a little later than usual that this deservedly popular convention city may be visited at a pleasant season. Hotel Pfister, selected for the meeting of the Association, has ample accommodation for all members and offers special rates. Its rooms are airy, spacious, and well furnished; it has an excellent auditorium, a pleasant restaurant, and a large banqueting-hall. A full attendance at the meeting, which promises to be one of unusual interest, is earnestly desired. Will those members expecting to read papers, kindly send titles thereof to the Secretary as early as possible. It is announced with much satisfaction that Dr. Warren P. Lombard, Professor of Physiology in the University of Michigan, will deliver the annual address. This will have to do with Re-enforcement and Inhibition of Nervous Processes.

Cause of the Queen's Death.—The most authentic account of the cause of the Queen's death is that derived from the *British Medical Journal* as follows: "The Queen's health had been failing for the past twelve months. The symptoms were mainly of a dyspeptic kind and were accompanied by impaired general nutrition and periods of insomnia and later by occasional slight and transitory attacks of aphasia, the latter suggesting that the cerebral vessels had become damaged. Dyspepsia, which tended to lower her Majesty's original robust constitution, was especially marked during her last visit to Balmoral. It was there that the Queen first manifested distinct symptoms of brain fatigue and lost notably in weight. These symptoms continued at Windsor, where, in November and December, 1900, slight aphasic symptoms were first observed. They were always of an ephemeral kind and were not attended by any motor paralysis. The Queen suffered unusual fatigue on her journey to Osborne on December 18th, showing symptoms of nervous agitation and restlessness which lasted for two days. A few days before her final illness, transient but recurring symptoms of apathy and torpor with aphasic indications and increasing feebleness gave great uneasiness to her attending physicians.

On January 16th the Queen showed for the first time some symptoms of mental confusion. By an effort of the will, however, Her Majesty would for a time, as it were, command her brain to work, and the visitor of a few minutes would fail to observe signs of cerebral exhaustion. On Thursday of week before last the mental confusion was more marked with considerable drowsiness and a slight flattening was observed on the right side of the face. From this time on aphasia and facial paresis, although incomplete, were permanent. On Friday the Queen was a little brighter. On Saturday evening there was a relapse and graver symptoms, which, with remissions, continued until the end. It is important to note that, notwithstanding the great bodily weakness and cerebral exhaustion, the heart's action was steadily maintained to the last, the pulse at times evincing increased tension, but always regular and normal. Frequently the temperature was normal. Throughout the last few hours of life paresis of the pulmonary nerves set in, but the heart beat steadily to the end. Beyond the slight right facial flattening there was never any motor paralysis. Except for the occasional lapses, the mind cannot be said to have been clouded, and within a few minutes of her death the Queen recognized several members of her family."

Obituary.—Dr. James Watson Stronach, formerly a New York physician, died suddenly last week at his residence, 35 Romore place, Belleville. He was sixty-seven years old. Death was due to heart trouble. Dr. Stronach was born in Forres, Scotland, and came to this country in 1860. He was graduated from the College of Physicians and Surgeons in New York and practised for some time in this city.

Dr. William H. H. Parkhurst, eighty-eight years of age, died in Frankfort January 22d. He was one of the oldest doctors in the Mohawk Valley, having been in constant practice since 1839. During his later years he took great interest in the germ theory, and contributed very materially to researches in that direction.

Dr. Eliphalet Nott, a well-known physician, died at his home in Rexford's Flats, Saratoga County, January 22d, aged sixty-seven years. He was a nephew of the Rev. Dr. Nott, for many years President of Union College.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, January 19, 1901.

THE ANTI-TUBERCULOSIS MOVEMENT—FORTHCOMING CONGRESS ON TUBERCULOSIS ACTIVITY OF THE NATIONAL ASSOCIATION FOR THE PREVENTION OF CONSUMPTION—A CENTURY OF MEDICINE—PROGRESS OF CREMATION IN ENGLAND DEATHS FROM DRINKING ARSENICAL BEER.

A British Congress on Tuberculosis will be opened in London on July 22d, 1901. It will be held from Monday, July 22d, to Friday, July 26th. Every British colony and dependency will be invited to send delegates, while the Governments of Europe, Asia, and America are invited to send representative men of science and others, who will be guests of the Congress. Papers will be read and clinical and pathological demonstrations given, detailing medical and sanitary experience in the treatment of tuberculosis throughout the world. A museum will be a special feature of the Congress and contain pathological and bacteriological collections, charts, models, and other exhibits from widespread sources. Authorities in this and other countries will be invited to supply documents on the historical, geographical and statistical aspects of the subject. Practical resolutions will be formulated to indicate the public and private measures best adapted for the suppression of tuberculosis. The work will divided into four sections, as follows: Section I., state and municipal, President, Right Hon. Sir Herbert Maxwell, M. P.; Section II., medical, including climatology and sanatoria, President, Sir R. Douglas Powell, Bart.; Section III., pathology including bacteriology, President, Prof. Sims Woodhead, M.D.; Section IV., veterinary, President, Sir George Brown, C. B. The Secretary of the Committee having charge of the museum is Dr. W. G. Horne, 27 New Cavendish street, Harley Street, London, W., to whom all communications relative to the museum should be addressed.

The National Association for the Prevention of Consumption and Other Forms of Tuberculosis is issuing to corporations, urban and rural councils, boards of guardians, medical officers of health, and other sanitary authorities, suggestions in respect of voluntary notification and of provision for open-air treatment for pauper consumptives. A number of towns have adopted notification. Where the usual notification fees are paid the system appears to have been successful; where they are not, unsatisfactory. The advantages of notification are shown in a tabular form under the headings, "What would be learned" and "What might be done." The latter includes isolation, improvement of insanitary areas and houses, disinfection of consumptives rooms, and the improvement of cowsheds. Useful information as to the present provision for the sanatorium treatment of poor consumptives and the cost of erecting sanatoria, is also given. A number of hospitals now provide open-air treatment for the poor, either free or at a small cost. Boards of guardians are beginning to make provision for the maintenance of beds in existing sanatoria or by adapting special wards in the infirmaries or by erecting their own sanatoria. The main equipments in the construction of sanatoria for pauper consumptives are summarized by the architect of the London Open-Air Sanatorium Association, and the cost of erection and maintenance of existing sanatoria is given.

The beginning of the new century is signalized in the press by a retrospect of the past one and a description of the extraordinary scientific progress which marks it as *the* century of science. In these articles the progress of medical science has received due attention. When the present conditions are compared with those at the beginning of the nineteenth century the contrast is startling. Then sanitation was neglected and the mortality of large towns was tremendous. Owing partly to the "window tax" houses were dark and ill-ventilated. In hospitals gangrene was rife, nursing as now understood was unknown, cleanliness was not thought of and the conditions in many respects tended to foster rather than prevent disease. Vaccination was only in its infancy and the average annual death-rate from smallpox was 3 per 1000. Nearly one-tenth of all the deaths in London were from this disease and the majority of the victims were young. The treatment of the insane was barbarous; they were loaded with chains, beaten, half-starved, and neglected. Ordinary patients, too, suffered much at the hands of the doctors. They were bled and blistered to a most pernicious extent and forced to take large quantities of powerful drugs the action of which was little understood. The nineteenth century has been marked by the displacement in medicine of vague and fantastic theories by a science built on observation. In France the brilliant Bichat, although he died at thirty, founded the science of histology. A few years later Corvisart published a French translation of Auenbrugger's pamphlet on chest diseases, in which was pointed out for the first time the fact that abnormalities beneath the chest-wall could be detected by percussion. Eight years later Laennec invented the stethoscope and inaugurated a new era in clinical medicine. Then came Jenner's discovery of vaccination. The Apothecaries' Act of 1815 had a most beneficial effect upon the education of English medical men. Previously there was no compulsory form of training. In surgery the beginning of the century was made memorable in England by the great names of Cooper, Bell, Colles, and Abernethey. In 1838 the office of register-general was established in England. The government then slowly came to recognize that they had duties in ensuring the health of the public. Clinical medicine was greatly ad-

vanced by Trousseau in France and Sir William Watson in England who not only made valuable observations, but disseminated their knowledge by brilliant lectures. At this time, too, lived Graves of Dublin, "the prince of clinicians," chiefly remembered by the disease which bears his name, but who desired that his tombstone should bear the inscription "He fed fevers." Three physicians of Guy's Hospital, Hodgkin, Bright, and Addison, the discoverers of the diseases which bear their names, and Bennet, who first observed the characteristics of leucocythemia, made British medicine famous throughout Europe. But the most valuable of all the discoveries of the middle of the century was anesthesia. Before its advent a patient awaited operation as a criminal did execution. In 1846 Wells and Morton discovered the use of ether and in the following year Sir James Simpson, the use of chloroform. The germ-theory of disease established by the immortal researches of Pasteur and its invaluable fruit, the antiseptic system of Lister, are too recent to require comment.

Cremation is becoming more popular in England and has at last been established on a commercial basis. The Cremation Society of England commenced operations at Wolsing in 1885, when only three bodies were incinerated. Since then the number has gradually increased. In 1894 the number was 101; in 1899, 240; and in 1900, 301. Of course these numbers are very small when the population is taken into account. But it must be remembered that the only crematorium available is inconvenient and expensive. The cost has been greatly reduced in the last ten years, but is still too high. A fresh chapter in the history of the movement has now been started. The London Cremation Society has been started which believes that cremation may be profitably placed on a commercial basis. A freehold site has been purchased at Hendon just outside the boundary of London. Two or three crematoria at first will be erected, on the newest and most approved principles, with a chapel, waiting-rooms, attendants' lodges, and provision for the erection of private as well as public buildings for the reception of cinerary urns. At Hull the first municipal crematorium in England has been erected at a cost of £2,500.

Four more deaths from poisoning by arsenical beer have been reported to the Manchester coroner. All occurred at the workhouse hospital. Ten more summonses were issued against publicans for having sold contaminated beer after the issue of a warning. Another fatal case occurred near Spalding, the victim being a young laborer. Inquests have been held at Salford (near Manchester) upon the bodies of two women whose deaths it was alleged were accelerated by arsenic poisoning. The medical evidence showed that they had suffered from pains in the hands and feet and pigmentation of the skin. In one case the verdict was, "Death from bronchitis, but hastened by alcoholic neuritis;" in the other, "death from arsenical poisoning." Since the discovery of arsenical poisoning from beer-drinking, the Manchester coroner has held twenty-one inquests. In eight cases death was found to be due to arsenical poisoning, in seven to natural causes, but with symptoms of arsenical intoxication, and in two death was accelerated by arsenical poisoning.

SOCIETY PROCEEDINGS

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The Ninety-fifth Annual Meeting, Held at Albany, January 29th, 30th and 31st, 1901.

FIRST DAY—JANUARY 29TH.

MORNING SESSION.

Inaugural Address.—The President of the Society, Dr. A. M. Phelps of New York, opened the meeting with his inaugural address and made among other recommendations these as of special importance. In view of the large amount of work falling to the Chairman of the Legislative Committee, who, on account of the intimate relation between the activities of the two offices, should also be the Assistant Secretary of the Society, he thought an annual salary of $500 should be voted. Without some such reasonable stipend it is almost impossible to find the right man for the place, able and willing to give his energy and time gratis. The old method of making members of the Society answered well when the organization had the granting and revoking of licenses within its power. Now that such functions are properly vested in the Board of Regents, other considerations make an enlarged membership desirable; for instance, the division of the body into sections for research. Instead of there being one delegate for a three-year term from each assembly district, at the end of such term eligible for membership, let there be two delegates for a one-year term each. In this way during the next three years a large increase of members will occur and then sections can be recognized. The Society should have 3000 members in this State which shows one-eighth of the total number of physicians of the State.

The wisdom of holding the annual meeting during the January deliberations of the Legislature is manifest, so as to impress the opinions of the Society upon that body. It would be very wise in the name of more purely scientific and social relations to have a second meeting each year to be held in turn in the cities of the first class. The Society possesses no office as such of assistant secretary, but by change in the Constitution and By-Laws this should be created. Such incumbent should collaborate with the Secretary and for convenience be the Chairman

of the Legislative Committee, as explained at the opening of this address. There is a bill before the Legislature now introduced by Senator Grady of New York, providing that all suits for hospital malpractice shall be against the medical attendant and not against the institution. The manifest unfairness of this in the face of facts, so well known about the relations of medical appointees to their hospitals as not to need mention, make it necessary for every medical factor in the State, individual and organized, to enlist himself strongly to defeat the measure. The union of the medical profession in the Pacific and Mississippi Valley States into their respective societies emphasizes the lack of a corresponding society in the Atlantic States, although 60 per cent. of all the American physicians dwell within them. Action should at once be taken by appointing a committee to open negotiations and, if possible, perfect arrangements. The wise legislation corrective of the notorious tenement abuses should be furthered by the Society in every possible way. Fitting tribute should be paid by the Society to the deceased honorary members, J. M. Da Costa, A. Stillé and S. F. Purple, and the deceased permanent members, W. M. Smith (long-time secretary), L. C. Gray, H. D. Noyes, and H. T. Hanks.

Executive Session. — Drs. Ely (Rochester) Vanderveer (Albany) and Van Fleet (New York) were appointed a committee to act on the recommendations of the President. Drs. Roosa (New York) McDonald (Albany) and Rowe (Rochester) were named as commission for nominating members for vacancies in the Board of State Examiners. The report of the Committee on Publication was adopted. It recommended the publication of the Transactions of the Society at $1.00 per volume, as last year, in order to put it further within the means of every practitioner. The recommendation of the Committee on Ethics was to admit to representation in the Society the following local bodies: Gloversville and Johnstown Medical Society, Medical Society of Long Island, German Medical Society of Brooklyn, and the West End Medical Society of New York. The Committee on Hygiene reported the law providing the establishment of a State sanatorium for consumptives and recommended the passage of laws for better housing of the poor; for the making of gonorrhea and syphilis amenable to the boards of health like all communicable diseases, subject to notice and registration; and for the better prevention of typhoid fever by improved water supply. A motion was carried making official the interest of the Society in the tenement-house reform. As Auditing Committee Dr. Bulkley (New York) Dr. Brush (Mt. Vernon) Dr. Elsner (Syracuse) were appointed, and their report was adopted in the afternoon. The Committee on Legislation recommended the appointment of a designated lawyer who shall by study familiarize himself with the medical laws and be in position to advise the Society better than any general lawyer not so specializing; also the support of the present bills before the Legislature, especially that defining the practice of medicine in this State. Its report was accepted. *Resolved*, That a special committee be appointed to appear before the Committee on Public Health of the Legislature in charge of this bill. Dr. Elsner of Syracuse was made chairman of this Committee with power to appoint his own associates.

Dr. C. A. L. Reed, President of the American Medical Association, was here welcomed and presented by the President of the Society. In his reply he dwelt on the advantages of unity and solidarity of the profession and mutual understanding on disputed questions. He praised the democracy of the New York State Society and advised further extension of it because the *strong* benefit the Society and the weak practitioners are benefited *by* the Society.

The Prize Committee made the award to Dr. Lucien Howe of Buffalo for his essay on "The Measurement of the Interlocular Base Line and the Size of the Meter Angle." The Committee on the State Board of Medical Examiners made points of interstate reciprocity for licenses, of the superiority of the New York State Medical school graduates and the general good results of the license law since its enactment. On motion of Dr. Elsner of Syracuse a resolution was adopted committing the Society to combat the present effort of the Legislature to cut down estimates for the State care of the insane.

The following gentlemen were elected by districts to the nominating committee: Drs. A. Van der Veer, Albany, Chairman; 1st District, A. E. Davis, New York City; 2d District, W. H. Zabriskie, Glen Cove; 3d District, W. G. Tucker, Albany; 4th District, R. J. Wilding, Albany; 5th District, Nathan Jacobson, Syracuse; 6th District, L. Coville, Ithaca; 7th District, W. J. Herriman, Rochester; 8th District, H. R. Hotchkiss, Buffalo.

TUESDAY—AFTERNOON SESSION.

Pneumonia Therapeusis.—Recent progress in the treatment of acute lobar pneumonia was the topic discussed by Dr. J. K. Crook of New York. He stated that considerable activity in this field has been shown and about fifty contributions to the subject have appeared in literature during 1900. It is apparent, however, that no striking innovation and no great advance have been made in the recently-proposed plans of treatment. The fifty contributors are at variance as to many minor, but are unanimous as to the fundamental principles of treatment. This consensus can be summed up in three admonitions: (1) Put the patient into bed in as comfortable and well-ventilated a room as possible; (2) give him nutritious and digestible food in moderate, not overabundant quantity; (3) watch him carefully. There are no other routine measures applicable to all cases without exception. No patient should be

obstetrical paralysis, dislocation or fracture. Non-development has been assigned as a cause, but in six autopsies by Stone was not present. The differential diagnosis is all-important and quite simple. Careful examination will show the head of the humerus in place, then the condition must be paralysis. If the head is out there is dislocation. If all the bones are manifestly small, there is arrest of development. The symptoms are those of any subcoracoid or subspinous displacement, upper arm flexed, abducted, rotated inward, elbow flexed, forearm fully pronated, wrist and fingers flexed. The treatment is, if possible, non-operative reduction and its maintenance. If the deformity recurs persistently, then the open operation must be done. The conclusions are as follows: (1) Differentiate at the outset between dislocation and obstetrical paralysis. (2) Adopt treatment early, first reduction, then operation, if the former fails. (3) Every infant at birth should be examined for trouble in the bones, joints or nerves. (4) From the fact that fracture of the glenoid cavity was present in three of Phelps' cases and that the history of difficult labor is always present, it is likely that obstetrical paralysis proceeds from the same source and is not itself a cause of the displacement. Arrest of development is also in the same relation to this condition and is not to be assumed as present unless the whole shoulder girdle is also affected. (5) The prognosis of early operation is most excellent. (6) As in congenital hip, so in congenital shoulder dislocation, orthopedic apparatus is of very little value. An excavator, devised by Dijou, was shown and recommended as most serviceable for deepening and smoothing the cavity and edges of the glenoid cavity at the time of operation.

Appendicitis and Diseases of the Uterine Appendages.—Dr. Albert L. Beahan of Canandaigua said that the occurrence of right-side pelvic disease in which the question arises as to the diagnosis between disease of appendix and appendages is frequent and sometimes requires fine distinction. Gross changes in the appendages resulting from disease coexisting with appendicitis are not uncommon. There has not been shown to be any close relation, except of proximity. Functional disease, with disturbance of menses, a dysmenorrhea, exists as a law of cause and effect. Four patients in hospital at the same time recently, unmarried women from seventeen to twenty-three years of age, had had irregular, painful menses. In one of these cases in which an anomaly existed of the appendix passing for a short distance between the coats of the intestine, making a tight stricture, the menstruation had always been painful, and recently a local peritonitis had occurred at the menstrual epoch. Our case-records, other than these four, show that these are not coincidences. A locked or torpid colon, with gas accumulations, an exaggeration of menstrual phenomena, increased pallor, or muddy complexion, languor, pains, nausea or vomiting, pronounced nervous irritability, peevishness, with febrile rise to 99.2° or 100.2° F., especially a single dose of medicine simply because he has pneumonia. Watch for and follow the indications. Recent observers are not a unit as to the best procedure for meeting the needs of the patient, but agree that a careful practitioner can easily outline a course suitable for each case. There is at the present time a distinct tendency to revert to the once time-honored and lately almost entirely-abandoned treatment by bloodletting. All writers admit that the reaction against this measure had gone too far and that a discriminating employment of it is now fitting, because no known procedure will so quickly and fully relieve an overcharged and staggering heart as the withdrawal of a few ounces of blood. The use of cold applications, as by ice-bags and sponge-baths, is now almost universal, and no measure of comfort is recognized as safer in employment and happier in its grateful effects. Arterial sedatives are losing in favor with some and gaining with other trusted teachers. The use of opiates is recommended by some and decried by others. The mean seems to be careful observation for direct indications, such as obstinate insomnia, active nervous disturbance and actual delirium, and then rational fearless administration. Alcohol in drunkards and seniles is good routine treatment, but in the robust should be used only when the pulse is weakened or accelerated. Few such patients with a pulse of 110 require alcohol. Among cardiac stimulants digitalis is less and less in favor, caffeine is much more popular than formerly and strychnine is probably the best for all-round work. The use of drugs supposed to be specific against the pneumococcus has gained little or no endorsement during 1900. Several reports of their successful exhibition have been made, but have really done little to advance the method. The antipneumotoxin plan has had few supporters among the Germans and French this year, but rather many in our own country and some very instructive data collected as to encouraging use both of pneumococcus cultures and of animal serum. Medicine is still face to face with the inability of the experimenters to elaborate an antitoxin of reliable, uniform and stable constitution. Until this obstacle is removed this department of the therapeusis of pneumonia must remain unorganized.

Dr. Bridges of Ogdensburg in discussing said that not all pneumonias are due to the coccus; the disease is often infectious and epidemic. The treatment is solely good nursing, fresh air, opiates, strychnine and alcohol.

Congenital Dislocation of the Shoulder.—Dr. D. W. Marston of New York said that this condition appears to have escaped minute observation up to the present. In literature Phelps since April, 1895, reports 4 cases, Eve since August, 1895, 1, Küster 1 (fatal). Stimpson, Post, Schedé and Stone 1 each. Gaillard had 1 and Phelps 2 cases curable by non-operative reduction. The causes are (1) trauma before or during delivery, (2) prenatal disease, as tuberculosis, osteomyclitis, etc., *in utero*. Difficult delivery may cause either

cially during the latter part of the day, if a tender, enlarged appendix is found, establishes the diagnosis. A recurrence of this group of symptoms at one or more succeeding menstruations may be expected. A hovering of the temperature about the 99.2° F. mark has come to be the clinching test. The tolerance of the female pelvis to disease should not mask the diagnosis, nor should a serious attack of appendicitis be permitted. Remove the appendix early. It will be a surprise to see its condition and a gratification that it was done.

Small Hospitals and Their Administration.—Dr. L. N. Lanehart of Hempstead pleaded for the existence and administration of the small hospital in the small community the following points: Their justification lies in the need of every town for an institution to care humanely and properly for the sick poor and incidentally for such as in virtue of the character of their malady need hospital surroundings. The benefits arising from such is proportionately as great as in large cities. As to the organization, the hospital should be incorporated so as to receive gifts and bequests and hold land. In this State it should enjoy the approval of the State Board of Charities. The board of managers should be relatively large for the more even distribution of work, conveniently thirty, divided into groups of ten each, serving respectively one, two and three years and thereafter elected for three years. Thus the greatest permanency is acquired for it. When practicable business-men and the members of the medical staff should be members, together with the women of the community. The president should be tactful and sensible. Women are best for house, wardrobe, visiting and training-school committee work. The chairman of each should have a place on the executive committee, the other members of which should be the titled officers of the association and the chairman of the medical staff. If such are all men the executive committee will be well balanced. The matron should be a graduate nurse, of good character and given absolute authority in her sphere. Complaints for the sake of the institution should always be handed to the executive committee for decision. The medical board shall be made up of physicians, surgeons, a pathologist, neurologist, ophthalmologist, aurist and laryngologist. These specialists may be rapidly developed, if necessary, or secured as consultants. To the staff the hospital offers the great advantages of association and to the community those of an educator in hygiene and broad medical knowledge. The support of the hospital is a difficult problem and may be in part solved by laws providing that the superintendent or overseer of the county poor shall be empowered to send to the hospital at the public expense all cases needing treatment in an institution.

Application of Vasodilators.—Dr. L. F. Bishop, of New York, made the subject of his paper the necessity of greater conservatism in the use of vasodilators in certain cardiovascular disease. The primary necessity here is as always to treat the patient, not the disease, namely, to estimate and combat the pathological conditions exhibited by him as a special case. The amount of the drug and the time and method of its application depend upon such knowledge. In cardiovascular disease it must be remembered that the heart is merely a muscular dilatation of the vascular tube and shares at the same time the kind and degree of the arterial disease. Tension in the arteries is due to some interruption in the muscular balance in the channels due to parietal, hemic or nervous causes. To restore this balance as rationally and fully as possible is the function of the drug. Hence we must determine always how much, how often and how long shall the drug influence be sought. Again while carrying on this proper medication the hygiene of all treatment must be minutely observed, namely, in a proper proportion of bodily rest and work, in proper food dependent upon the character of the disease fundamental to the cardiovascular lesions, as, for example, nephritis and rheumatism, and, finally, in proper rational living in all relations. Having decided these points care must be exercised to use only the most reliable preparations. In conclusion we must remember that there is absolutely no specific in cardiovascular disease and that our sole object is to compensate for errors in the circulation, and having secured that to maintain it carefully. Successfully done this is all that can be hoped for, on account of the intrinsic pathology of these diseases.

What is Rodent Ulcer?—Dr. J. A. Fordyce of New York read a paper with this title and showed a number of photographs illustrating the clinical as well as the histological features of this affection. He referred to the differential diagnosis of late syphilitic ulceration of the skin, lupus vulgaris (tuberculosis cutis), and the disease in question. He stated that mistakes in diagnosis not infrequently came under his observation. These mistakes in diagnosis are more frequently made in the late stages of this type of cutaneous cancer when it sometimes loses its pearly-gray, ridge-like margin and only appears as a more or less extensive ulcer. The age at which it begins also leads to mistaken ideas as to its nature, for although in the majority of cases it makes its first appearance near the age of forty, it not infrequently begins much earlier in life. The writer has seen it begin about the age of twenty and Hutchinson has reported a case which appeared when the patient was fourteen. Rodent ulcer differs from other types of cutaneous cancer in its apparently insignificant early stage, its excessively slow course and in the absence of little new growth. The ulceration keeps pace with or exceeds the newly formed tissue and thus justifies the clinical name with which it has so long been identified. While possessing little power to infect the general economy, rodent ulcer, when well established, shows a remarkable tendency to recur after removal whether the interference be by surgical or the so-called dermatological methods. That the lymph-nodes are not always spared was shown by a case which the writer had observed in which the lymph-node over the mastoid had been infected by a rodent ulcer behind the ear. The

patient was also afflicted with a rodent ulcer in the typical location, *i. e.*, on the side of the nose extending to the inner canthus.

Rectocolonic Enteroliths and Concretions.—Dr. S. J. Gant of New York said the occurrence of these objects is most common in female adults and in the rectum, although any part of the gut may be their host. Their composition is usually that of true enterolith, hair-ball, gall-stone, urinary pancreatic and prostatic calculi and such miscellaneous material as fruit-seeds, etc. Hair and wood-fiber have both been found in the human, the latter proceeding from toothpick chewing. Stones made of oat and potato-peel fiber are common among the Scotch poor. Gall-stones are very common indeed, and more than any other type of these concretions. The true enterolith (not gall-stones) are found especially in females, single or multiple, weighing from grains to ounces, oftenest in the rectum, colon and small intestine in the named order. Their chemistry is phosphate of lime and magnesia, ammonia and organic matter. Pancreatic concretions are small and brittle and enter by ulceration from the pancreatic ducts. Urinary calculi commonly appear from the ureters into the rectum by erosion. Impacted feces are familiar to all. Prostatic calculi simulate the urinary in route and symptoms. Masses of fruit seeds occur chiefly in the summer when fruit is eaten and usually in children, particularly in the bowels. The symptoms agree with the site of arrest, the number and size of the stones, the duration of their presence, and the lesions of the intestines actually caused by the stones. In brief they are those of intestinal irritation or obstruction depending in degree and results upon circumstances. The treatment is removal by means indicated by the factors present and preventive medication.

Esophoria or Latent Squint.—This was the subject of a paper by Dr. F. Valk of New York. The writer does not believe in the old theory of Donders that hypermetropia is the cause of convergent, nor that myopia is the cause of divergent squint, as there are so many cases that will disprove this theory; nor does he accept the innervation theory of Hansen Grut, but does base his opinions on the so-called muscular theory, associated with the fusion force of the eye. He believes in the power of the straight muscles of the eyes, as shown by their insertion, size and weight, in which one muscle must show a certain power to act under the stimulation of the fusion force and that this power should bear a certain relation or ratio to the action of the other muscles. This power is shown by the prism test, an old and reliable one, and in the writer's opinion, the only one that can be depended upon to indicate properly the true balance of power in these muscles or the want of power, as an unbalance and the probable muscles that are at fault while all other tests can only be used or depended upon simply as confirmatory of this one. That in the relation of these muscles, one to the other, he excepts the abduction, as compared to adduction, as one to three or four and that outside of these limits there may be latent squints. He accepts this ratio as standard. That after testing the muscles by this method one frequently finds homonymous diplopia with the red glass before one eye, a condition indicating the advisability of an operation.

The writer then gives short histories of sixteen cases showing latent convergent squint by the prism test, operated upon with success. The operation consists of a shortening of the external rectus by a "tuck" with a catgut suture, which is inserted while the muscle is held by the twin strabismus hooks, devised by himself. The catgut is allowed to be absorbed and the reaction, if any, is very slight.

Dr. L. Howe of Buffalo said that the estimate of the relation between the muscles must not be too definitely and fixedly adjudged. Otherwise there is danger in making operation the chief cure of such conditions as esophoria which are within reach of other means.

Demonstration of Ophthalmophakometer.—The following technical points were elucidated by Dr. L. Howe of Buffalo on this topic. The first object of this communication was to illustrate the working of Tscherning's opthalmophakometer, no similar instrument having been used before in America for viewing the entoptic images. A brief description accompanied the instrument and was in general the same as that given by its originator in his book on "Physiological Optics" translated into English by Weiland. The second part of the communication related to a simple formula by which it was possible to calculate rapidly and exactly the depth of the anterior chamber; the center of curvature of the anterior surface of the crystalline lense; the center of curvature of the posterior surface of the crystalline lense; the distance of this center of curvature from the posterior surface of the cornea. The third point in the paper was to describe a modification of the phakometer made by the writer. This consists in a change in the telescope by which the former inverted image is changed to an erect image, the magnification being the same or slightly greater. By this means, with a proper arrangement of the light, it is much easier to recognize and study the movement of the entoptic images.

Syphilitic Interstitial Keratitis.—Can interstitial keratitis be prevented in the offspring of syphilitic parents? This was the question propounded and answered in the following terms by Dr. P. A. Callan of New York. It is a fair assumption that syphilis is responsible for the majority of cases of this disease, rarely in its acquired forms, but rather commonly in its inherited manifestations. It usually appears in the latter type during the growing period and has been seen by the writer as early as the fourth and as late as the twenty-eighth year. The offspring of syphilitics who survive the fifth year present few or no marks of the inherited taint. The typical face, that of premature age, is rarely seen. Hutchinsonian teeth are more frequently met, but not such as the textbooks describe. Their really distinguishing mark is the peg-like incisors, the small notched ones are very uncommon. Ordinarily there is nothing about

such children to indicate their hereditary taint prior to the affection of the eyes. The inflammation affects both eyes with an interval of about a month, however, in some cases this may be a period of years. Treatment may prolong this interval, but in the writer's experience sooner or later the second eye suffers. He tried in one young female to prevent the development of the keratitis. She had unmistakable symptoms of inherited syphilis, face and teeth both typical. For ten years he had her under observation and more or less regular treatment, and for one year under full tonic and antisyphilitic medication. Nevertheless, at the end of that time she developed a keratitis interstitialis of one eye and after a short interval of its fellow also. One member of a family of children may escape while all others suffer, and conversely one may be attacked and the balance be spared by this disease. There seems to be at present nothing to account for this peculiar discrimination. In conclusion, there is nothing to show syphilitic taint inherited from diseased parents *in the majority of such children as survive the fifth year.* Only a small percentage of such children ever develop this affection of the eyes. In the writer's experience it is impossible to prevent its appearance, at least in a certain number of cases. When one eye is attacked the other sooner or later suffers also.

Menstruation and the Skin.—Dr. L. K. Bulkley of New York considered the relations between certain diseases of the skin and the menstrual function. He said that during menstruation the woman passes through a most active psychical crisis which lasts ten days, beginning slowly, rising to an acme and decreasing to normal conditions also slowly. During this third part of each month her temperature rises, her total excretion of urea is changed, arterial tone is raised, digestion, nerve-function, with other systemic activities, are modified profoundly though temporarily. In many a species of auto-intoxication is present and the reflex and sympathetic nervous phenomena are manifest. At puberty and at the menopause for obvious reasons all or most of these disturbances are much increased, often to an almost pathologic degree. As to the skin he said that through seven years of recorded experience he has noted the influence of menstruation upon it, both in the absence and presence of functional and organic utero-ovarian disease. Forty-two are the total of these cases involving twelve diseases. Such effects are familiar to all at puberty. Acne makes up one-third of all these skin signs, especially on the chin, where it is almost pathognomonic. Eczema is the next best example, and in it exacerbations of chronic forms and even modifications of acute forms occurs at the epoch. In this disease the hands are the seat for most of these peculiar signs. To signify the relation of the skin to puberty he stated that eczema in females is twice as common as in males between the ages of fifteen and twenty years.

In the discussion Dr. Jacobi of New York said that he had in his forty or fifty years of professional life noted several distinct examples of vicarious menstruation present during amenorrhea, from the nose as distinct epistaxis, from varicose ulcers as obstinate oozing and one case from the ear which recurred monthly for nearly a year. He asked for Dr. Bulkley's observations on such cases. Dr. Boldt of New York asked the author for a theory of the cause of such vicarious activity. Dr. Bulkley said in reply that while he had often seen it he could offer no explanation.

Treatment of Chronic Otitis Media.—This was the subject of a paper by Dr. J. F. McKernon of New York. This paper will appear in full in the Medical News.

Hysterical Anesthesia and Analgesia.—Dr. B. C. Loveland of Syracuse reported a case of hysteria in which anesthesia is a prominent symptom, both from the extent and peculiarity of its distribution, and added some considerations in regard to anesthesia as a diagnostic sign. His case presented a complete anesthesia, involving tactile, pain, thermic and location sense, and the areas affected were as follows: Both legs and feet, the upper limit being the groin in front and the gluteal fold behind; both arms, hands and shoulders, the limit above being the collar-bone, and below a line just above the nipples in front, and the lower angle of the scapulæ behind. The patient also showed hyperesthesia over the lower half of the abdomen, and hysterogenic zones below her shoulder-blades on the back. Beside these symptoms there were several other characteristic stigmata of the disorder. He does not describe treatment at length, but used electricity, massage and mental suggestion, with isolation from the family, as important factors in his method. He concludes that anesthesia does not rank with globus or hyperesthesia in frequency, but when found is of marked diagnostic importance and should not be overlooked; that it usually follows a pronounced hysterical crisis and is seldom found in the milder cases; that it does not follow the distribution of any nerve or group of nerves. He then describes the various typical forms, and shows the case reported to be somewhat atypical. The writer also noted the frequent accompaniment of ischemia and the infrequent presence of paralysis in connection with this variety of anesthesia, and that anesthesia, more or less complete, is more frequently met with in cases of hysterical paralysis. When this occurs it conforms to the paralyzed member, contrary to that in organic paralysis of central origin.

Correction of Deformities Following Pott's Fracture.—Dr. W. O. Plimpton said that braces and other forms of support that have been devised for deformities following Pott's fracture are unsatisfactory in application, awkward to wear, and in no wise curative. Operative treatment offers the only means for permanent relief. The degree of dislocation, whether partial or complete, together with the exact relative position of the bones, determines the extent and nature of the operative measure necessary to overcome the deformity. Recent conditions are more easily corrected than late ones, in which fibrous tissue and

muscle have undergone change. In the early malpositions a reproduction of the original fractures by dividing the bones at the site of injury will usually suffice to restore the foot to a normal position. Cases of longer standing, that have undergone change of soft parts of bony surfaces, must be dealt with as the conditions require to overcome deformity. No single operation will suffice for these cases. Do what is necessary, resect bones and cut soft parts to restore the foot to the perpendicular axis of the leg. Place the astragalus squarely on the horizontal plane of the tibia. Restore the mortise of the joint as perfectly as possible. Operations outside the joint like cuneiform or linear osteotomy, do not reduce the dislocations, but simply produce a new deformity to help out another by averaging the deflection of the foot from the axis of the leg with the line of the new position, and are therefore not to be recommended. If resection becomes necessary, confine it to one side of the joint, if possible. By saving the cartilage opposite the cut surface of bone, ankylosis may be avoided. The X-ray will assist by showing the operator what he will have to deal with and aid him in formulating a plan of procedure. Suit the operation to the case at hand for the restoration of the foot to the normal axis of the leg.

Deep Breathing.—Upon the subject of deep voluntary breathing as a curative and preventive measure Dr. J. H. Pryor of Buffalo established the following points: Its importance can not be overestimated, because in modern civilization few of us after childhood breathe deeply. Yet this full lung function means, first, all the proper oxygenation of the blood and its therapeusis is in brief the same as oxygen in the system. At any time of life and for either sex better lung action would be undoubtedly of great value; and in disorders of the blood in which purification and added tone are required it will on trial be found a great adjuvant of other rational therapeutic means. Among such conditions are to be mentioned chlorosis, anemia, and the depreciated states after severe illnesses. When the lungs intrinsically show deficient action, as in the muscularly feeble, or when after disease, especially the various forms of pleurisy, pneumonia and bronchitis, their sequelæ and complications, they are found imperfect in function, it is exceedingly probable that most or entirely all of the difficulty can be eradicated or compensated for by training in forced voluntary respiration several times each day. In children very likely the deformities of the chest incident upon rickets and similar disease could be in part neutralized by proper breathing gymnastics. In the subacute forms of bronchitis and pneumonia we have the air-vesicles glued together with exudate. By opening these, absorption and even discharge of the exudate by expectoration will be initiated and stimulated. In some of the old semi-consolidations of pneumonia a like process obtains, added to the advantage of general stimulation by this process. It is closely analogous to the similar results of massage of joints. This might be called lung massage. Cough is not a contra-indication, in fact has the advantages of expelling exudate. For the inhalation various soothing remedies can be added to the air. The patient should repeat this exercise several times daily.

Dr. J. Riddle Goffe of New York City stated that he had seen great success follow this plan among chlorotic girls. Dr. Styles added that morning exercise and hill-climbing in the erect position are beneficial. Dr. Hopkins of Buffalo recommends horseback-riding as compelling deep respiration. Dr. Goodwillie of New York said that normal alimentation and respiration determine health. Deep breathing is a kind of massage to all the viscera. Dr. Potter of Rochester finds cycling valuable. Trapeze exercise also increases chest diameters and function, also overhead respiratory work.

Indications for Mastoid Operation.—Dr. W. C. Phillips of New York referred to the fact that in selecting the time for operation in mastoid diseases the judgment is frequently severely tested. Opinions vary from operating at the time of invasion of the mastoid to a delay which may lead to extensive complications. There really must be a period in every case when operation should no longer be delayed and his object was to outline those symptoms which point to the desirability of operative interference. All operators cannot absolutely agree with any single opinion. He discussed the indications for operating upon the mastoid in acute cases and emphasized the fact that just at this time mastoid disease is prevalent, secondary to the grip. Whenever mastoid complications are attended by the presence of streptococci, staphylcocci or pneumococci in the pus, the danger of rapid extension of the disease is imminent. In all mastoid cases a microscopical examination of the pus should be resorted to. He described acute mastoid suppuration as an involvement of the bone appearing during the course of acute suppuration of the middle ear. The symptoms are pain, fulness over the entire parietal region and tenderness, especially over the antrum and tip. Temperature should always be considered, but is not an all-important symptom. External periostitis, with or without infiltration of the soft tissues, is a later development. Bulging in the atticus tympanicus and the superior wall of the external canal is generally present. Suppuration of the mastoid should be considered as a complication of suppuration of the middle ear, but further complications were occasionally found, as extension into the surrounding tissues, especially the lateral sinus or some portion of the cerebral cavity. Local bloodletting, real or artificial leeches, ice-coils, hot poultices, and hot-water irrigation are preventive methods. Ice-coils should not be used longer than twenty-four to thirty-six hours. The mastoid operations should be performed in acute suppuration when no permanent remission of symptoms has followed free drainage through the drum or the application of ice-coils, poultices or free local bloodletting. Then

there should be absolutely no delay. It is at this very point that many otologists wavered. The exact time for operating may not be measured by days or hours. In grip cases the destructive process is so rapid that one frequently needs to operate soon after the invasion. He mentioned a recent case of a child, eight years of age, in which he had found it necessary to operate three days after the first mastoid symptoms and found pus, not only in the antrum, but also in the tip. In chronic cases, after all other treatment has failed, it frequently becomes necessary to operate in order to overcome the discharge. Life insurance companies will not accept as risks those who suffered from chronic discharge of the ear.

Belladonna versus Scopolia.—Dr. R. W. Wilcox of New York read this paper. This will appear in full in the Medical News.

Indications and Limitations of the Vaginal Operation in Pelvic Diseases in Women.—Dr. J. Riddle Goffe of New York took the position that any operation that can be done as safely and satisfactorily for the patient *per vaginam* as by the abdomen should be done by that method. The dangers are incomparably less, the convalescence is smooth and the after-treatment simple, the patient being relieved of stitches, adhesive plaster, abdominal binder and dressings. There is no visible scar to continually remind the patient of her experiences, and, above all, there is no danger of hernia. Practically, vaginal hernia or enterocele is an unknown sequela of vaginal section, while cases of ventral hernia following abdominal section, even for the relief of the simplest forms of pelvic disease, are constantly presenting themselves. Personal experience and the careful study of the experience of other operators, both in gynecologic and general surgery, have led the author to the conclusion that the only justifiable radical operation for cancer of the uterus is vaginal hysterectomy. The radical operation through the abdominal incision, which consists in ligating the large blood-vessels of the pelvis and rimming out all of the cellular tissue and lymphatics, with the hope of heading off the invasion before it shall have involved the general system, is an *ignis fatuus* that will shorten the lives of many women and lure the operators on to greater destruction. Examination of the statistics of these operators reveals the fact that the patients thus operated upon (provided they survived the immediate operation) are either all dead, or about to die, or sufficient time has not elapsed since the operation to indicate what the results may be. In the treatment of fibroid tumors the author advocates the vaginal route of attack for either myomectomy or hysterectomy whenever the neoplasm, whether single or multiple, is confined to the true pelvis. In those in which the tumor is sufficiently large to rise out of the pelvis the abdominal operation is preferred. Several cases were reported to illustrate these points. In salpingitis and ovarian abscess, whether single or double, the vaginal method is advocated, and also in displacements of the uterus, in the treatment of which condition, whether complicated or simple, the author considers the shortening of the round ligaments *per vaginam* as the most ideal treatment that had yet been suggested.

In the discussion Dr. Boldt of New York said that the operations for cancer of the uterus should not be confined to the vaginal route, because infection by direct contact with the neoplasm-cells is not yet proved. In interstitial myoma the abdominal route is better for space, and in tubal disease is more rational to avoid complications. Dr. Scully of Rome said that post-operative abdominal hernia can be prevented by care. Dr. Cordier of Kansas City said that complications, accidents and associated lesions can be best treated by the abdominal route.

Disinfection in Diphtheria. — Dr. M. A. Veeder of Lyons discussed disinfection within and without the body in this disease. There are three similar and easily-confused diseases, namely, diphtheroid, true diphtheria, and septicemic sore throat. The first is caused by staphylococci, the second by bacillus diphtheriæ (Klebs-Loeffler) and the third by streptococci. These may be separate, associate or consequent diseases, the graver following the milder forms. The septicemic sore throat is most deadly as a rule, although true diphtheria may be virulent and fatal. Both should be treated by local germicides, isolation of patient, thorough disinfection of articles in contact with the patient, and destruction of all nose, mouth and throat excreta and any other possible source of spread of the disease. Diphtheroid is itself not often a serious or troublesome malady, but becomes important because of its clinical relation to true diphtheria, namely, as precursor. True diphtheria can be carried by the practitioner to himself and to other members of the family and community by too frequent and improperly conducted examinations and by too little personal care after such of his hands, face and clothing. The cough of patients is capable of sending many bacteria the distance of yards into the room. Hence such cough should be turned away from others. The throats of all attendants and members of the same household should be regularly examined to determine whether they be infected, although the individuals are not yet clinically ill. An adequate protection, in his experience, is for the doctor to place a moist mask of gauze over the whole face while making his examination. The mask should each time be burned. A bichloride-of-mercury wash for hands and face should next be used.

After-Thoughts on Diphtheria.—The dread of this disease by patients early enlisted his interest, said Dr. I. N. Love of New York, and the changes of attitude toward it have been noted for fifteen years by him. The discovery of the real cause of the malady by bacteriology was the first great change, followed soon by the development of the antitoxin theory. This antitoxin method of treatment will probably be found, as the years pass, more or less available in a large number of diseases, as, for example, pneumonia, typhoid, tetanus and smallpox, and perhaps ultimately to

all infectious diseases. But credit to it must not overshadow what is due to other improved methods of treatment in hygiene, antisepsis, nourishment and stimulation. It is wise to regard every sore throat as the possible ground upon which a diphtheria may grow and hence to treat them all with this point in mind, by local antiseptics and germicides. The benzoate of soda and bichloride of mercury are invaluable in this connection. Healthy mouths may contain the bacillus, and before the discoveries of bacteriology simple inflammation of the throat went under their right names, which have all become *diphtheria* if the organism be present. Deaths by antitoxin, through impurities or even inexplicable cause, are known, hence its use should be guarded. Best try in addition or even in preference full isolation, thorough disinfection, sensible hygiene and local applications.

Persistent Suprapubic Vesical Fistula.—The treatment of this condition by the Bottini operation occupied the attention of Dr. Willie Meyer of New York through an interesting case which he reported. Three such operations were done, the last by himself, on this patient and permanent cure resulted. The possibilities of this method, when persistence of the fistula depends on prostatic obstruction, are at once apparent.

Fatty Degeneration of the Heart.—Dr. T. E. Satterthwaite of New York read a paper on this subject. (See page 165.)

The Porro-Cesarean Operation.—Dr. J. H. Glass of Utica presented the following as the indications for this operation: (1) Sepsis, actual or suspected after protracted labor or faulty technic of the attendant; (2) cancer of the cervix or lower uterine zone; (3) myomata of the body in selected cases; (4) atresia vaginæ if otherwise no remediable; (5) tumors of the ovary; (6) hemorrhage not otherwise controllable; (7) an insurmountable cause of maternal dystocia.

Recent Experiences With Erythromelalgia.—Dr. H. L. Elsner of Syracuse read this paper. It will appear in full in a subsequent issue of the MEDICAL NEWS.

Results Following the Cure of Chronic Defects of the Vesical Function.—This paper was read by Dr. Eugene Fuller of New York, who said that while a normal bladder empties itself completely at each urinary act, there were numerous factors which served to cripple that function and such, if long established, produce pathological changes in the urinary tract. His article was to illustrate the fact that when such factors are removed the tendency is strongly toward repair. Among these factors are stricture, chronic contraction about the vesical neck, prostatic hypertrophy, calculi and tumors. The direct causes for these conditions were vesical tenesmus, stagnation of urine and urinary infection. Vesical tenesmus long continued against a slowly-increasing obstruction causes hypertrophy of the bladder-wall, even to somewhat over half an inch. Such bladders are of firm and unyielding walls of contracted cavities and of small capacity. Stagnation causes distention, sometimes even rupture. An atonic bladder is one that has lost its contractility by overdistention. The function-crippling factor generally develops slowly, the muscular hyperplasia for some time keeping pace with the increasing obstruction, but at last the obstruction getting too great dilation and stretching begin. The appearance of such cavity is trabeculated and rugous, sometimes deeply sacculated. Chronic vesical stagnation, later affected also the ureters and renal pelvis, and the ureterovesical valves become so patulous as to be almost without resistance. The natural check to reflux is thus removed, hence the development of an intrapelvic pressure and of hydronephrosis. Where the hydronephrosis is extensive the kidney is involved and its function largely damaged. Vesical infection added, the inflammation first manifests itself by a cystitis. It is its ascent up the ureters and into the renal pelvis which was of chief importance. In the renal pelvis it is especially dangerous, because it cripples the renal function by involvement of the tubules. It is reasonable to suppose that these effects, especially if severe, will not immediately disappear after the crippling factor is removed, but it is surprising how soon normal conditions will be effected if the operation and after-treatment had been thoroughly performed. It is important to bear in mind that not only should the disturbing factor be removed, but also vesical rest through artificial drainage should be secured until the lesions in the urinary tract have had time to heal.

A Simple and Accurate Method of Substitute Infant Feeding.—This was the title of a paper read by Dr. H. D. Chapin of New York. There are three equally important factors in the preparation of a substitute for woman's milk: (1) Selection of good cow's milk; (2) modification of the milk with reference to percentages; (3) the choice of a diluent. Milk is rendered unfit for use by growth of certain kinds of bacteria. Growth of bacteria is prevented by cooling milk to below 60° F. Cooling milk also promotes separation of cream. If the milk is bottled right after milking, cream will be up by the time it is delivered to families. There is great variation in richness of milk and cream, but the same milkman's supply is quite uniform from day to day. Calculated mixtures of milk and cream are not accurate and only confuse, as standardized milk or cream can seldom be procured. What is at hand must be used. The variation of milk and cream in milk-bottles is seen in a bottle of milk on which the cream had risen. There are two great classes of milk: (1) That which forms hard solid curds with rennet—cow's and goat's milk; (2) that which forms soft flaky curds with rennet—woman's, mare's and ass's milk. Digestive enzymes act by contact and the food that is most finely divided and can most easily leave the stomach is the most suitable for weak digestions. The proteids of woman's milk easily leave the stomach. Little of the proteids of cow's milk diluted with

water can readily leave the stomach. Diluting with a wheat or barley gruel in which the starch has been digested breaks up the curds. Digested gruel is made by boiling a heaping teaspoonful of flour with a pint of water, cooling and adding an aqueous solution of diastase, that can be made at home from malted barley grains, or Cereo, a preparation of diastase made for this purpose. Specimens of milk diluted with water and digested wheat gruel, and curded by rennet were presented. The curds with digested gruel diluent passed through a sieve having 900 meshes to the square inch, those with water diluent remained on the sieve. Have milk bottled at the dairy. Dip off top nine to sixteen ounces into a pitcher or bowl. Here fat and proteids are in about same ratio as in woman's milk. If a siphon is used the sediment goes into the infant's food. Prepare the digested gruel. Make the infant's food one-eighth to one-third of nine ounces top milk or one-eighth to two-thirds of sixteen ounces top milk, the balance digested gruel. Add one part sugar to twenty or twenty-five parts food. Fine adjustments of percentages are not needed by this method. Nearly the same percentage results will be attained with any milk. Rich milk will be diluted more, poor milk less. Each additional ounce removed from milk-bottles reduces the fat in top milk .5 to 1 per cent., which cuts down the fat in infant's food ⅛ to ⅓ per cent., depending on the dilution.

TUESDAY—EVENING SESSION.

Primary Rupture of Ectopic Gestation.—Dr. G. McNaughton of Brooklyn said that in this abnormality the moment of primary rupture is that for opportune diagnosis. There are three types, ovarian, tubal and tubo-ovarian. The abnormal or ectopic pregnancy is a modern condition more and more recognized by the average practitioner. The writer has seen seventy cases in his own practice. The differential diagnosis is easy, but requires care in the history-taking and physical examination. In brief the early symptoms are those of pregnancy, actual or presumptive which persist for the first two or three weeks and finally comes the primary rupture of the tube either into uterus, adnexum or abdominal cavity, accompanied by pain or discomfort, signs of moderate or intense hemorrhage, and almost always a few ounces of blood through the uterus and vagina, even when the rupture is intra-abdominal. The physical examination shows a soft tender steadily increasing tumor as days and weeks pass until the final rupture. This tumor is almost pathognomonic. The site of ectopic pregnancy is almost always primarily the tube. Ovarian forms do not occur as such. The expulsion of the ovum may be into the uterus or cellular tissue of the adnexum or into the pelvic cavity. The first and third with or without and the second route always with rupture of the tube. Conditions simulating this one in the presence of normal pregnancy are (1) small soft ovarian cysts, especially pediculated and suddenly twisted on this base; (2) fibroids subserous soft and pediculated in the same way; (3) ovarian or tubal or tubo-ovarian abscess occasionally, but the presence of the inflammation differentiates; (4) acute appendicitis. Rupture occurs at about the sixth week. During the interval failure of menstruation or irregularities of it, then the steady pain or discomfort without fever. These are suggestive. Actual rupture has its clear picture. The treatment is to operate before rupture if possible. If rupture is suspected give aconite (no stimulation), ergot and belladonna. Operate at once. After this restore lost blood by saline solution and stimulate against the combined shock of the rupture and the interference.

Dr. Dawbarn of New York reported a case of disseminated abdominal sarcoma which closely simulated ectopic gestation and led to that diagnosis until the laparotomy corrected it.

Leprosy in the Hawaiian Islands.—This matter was reported in full by Dr. C. E. Davis, of Albany. In September, 1898, the writer accompanied the Annexation Commission to visit and inspect officially, the settlement and mode of living of the lepers on Molokai Island. The visit afforded an opportunity for a careful and complete observation of leprosy in all its forms. There are two leper colonies, namely, Kalaupapa and Kalawao, each a little village in itself. Molokai is probably the most complete settlement of its kind in the world and is maintained at a cost of about $90,000 a year. It has stores, markets, dispensaries and cottages for lepers. The majority of the lepers live in cottages, and in the settlement there is a total of 716 buildings. Liberal monthly rations are supplied by the Government. Official measures for the suppression of leprosy were adopted as early as 1865, when King Kamehameha sanctioned a public law providing for a portion of land to be set apart for the isolation of persons deemed, by official examiners, capable of spreading the disease, and for a hospital where persons in the incipient stages might be treated. From this beginning has developed the leper settlement of Molokai, with its hospitals and separate "homes." A year ago the number of inmates of the settlement was 1207; 61 of these being priests, sisters, etc.; 73 helpers, and 1073 lepers. The death-rate per annum varies greatly, often more dying during the year than had been admitted during the same period. Some years, however, the number of deaths is as low as 40 or 50 per cent. of the admissions. Among the causes of spread of the disease are the low moral standard of the natives, their filthy habits of using the same beds, clothing, pipe, dishes, etc., the custom of kissing and nose-rubbing; cohabitation, and bad sanitary surroundings. Vaccination with humanized virus, during the great epidemic of smallpox in 1852-53, is also said to have aided in the dissemination of leprosy. There are three prevailing types of the disease, the tuberculous, the anesthetic, and a mixed form. The symptoms of the first two differ widely, while the mixed

form, the most severe of all, manifests the symptoms common to both the other types. The period of incubation is generally from two to four years, but in some cases even longer. That leprosy is not hereditary is proved both by the very great percentage of nonleprous children of leprous parents, and by the fact that it is now known to be a parasitic disease. Among the many remedies used are chaulmoogra oil, gurgin oil, salol, arsenic, strychnine and creosote. Local applications of ichthyol, chrysarobin, salicylic acid, and goto lotion are also employed. Bacteriologist Hoffman has recently written a very important report on the hypodermic use of chaulmoogra oil. During the five months in which he has been experimenting with it, the results have been very gratifying. Rigid segregation has been the greatest safeguard against leprosy. Without it the disease would have been vastly more widespread undoubtedly among the whites as well as the natives.

Elbow Disability.—Dr. Samuel Lloyd of New York said that in damage about the elbow joint partial or complete loss of function in ankylosis is due to bony obstruction and very rarely indeed, never in his own observation, to fibrous tissue such bony substance may be callous in abnormal amount and unfortunate relation, or pieces of bone floating as foreign bodies in the joint cavity or most commonly faulty and misplaced fragments united to form a deformity. These last may consist of the epiphyses, condyles, head of the radius and base of the ulna and are common enough. The value of the X-ray comes in here to determine cause, degree and site of the obstruction in old and recent cases and to indicate the line of treatment and to verify its proper course and results while they are being established and still open to correction if faulty. The treatment of these cases is easily decided, primary immediate replacement by open operation when other means fail. In compound fracture one does not hesitate to invade an involved joint for replacement why should one not similarly open the joint in these irreducible and unreduced simple fractures? His own results by this method have been entirely satisfactory. The attitude for the after-treatment must be as full flexion as possible to avoid a helpless, useless member if a bad result in the joint supervene.

Dr. Dawbarn of New York said that in the swelling about the elbow so fatal to good diagnosis full anesthesia and the application of an Esmarch bandage from fingers to shoulder will be very serviceable in eliminating the edema. Passive motion should not be begun for about six weeks to avoid undue callous excitation. Dr. Beck of New York said that X-rays are alone the means of good diagnosis. Dr. Lloyd in closing said that three weeks are enough to acquire bony union, strong enough to stand slow gentle motion, to avoid stiff joint.

The Tonometer and Arterial Pressure.—Dr. H. L. K. Shaw of Albany read this paper. It will appear in full in the Medical News.

Pleuropericardial and Diaphragmic Adhesions.—Dr. D. H. Goodwillie of New York calls attention to the great frequency of interpleural pathological conditions as compared with other pulmonary diseases, as shown by physical examinations and autopsies. Pleuroplastic exudation, if not early recognized and removed by appropriate measures, thickens the pleuræ, organizes and forms adhesions between the costal and pulmonary pleura, the pericardium, diaphragm and pleura. These latter complications are of serious importance, and are not so readily recognized by the physical examination.

He insists on the importance of a very careful study and observation of rational and physical signs respecting interpleural pathology, the requirements respecting the auscultator having perfect hearing and ability to recognize, first, normal chest sounds and then the abnormal sounds which are in great variety and dependent upon the many pathological conditions. The necessity of a knowledge of the laws of acoustics as applied to the chest sounds, how they are conveyed and changed by passing through the various tissues from the point of inception within to the ear of the auscultator. In the year 1876 Dr. Goodwillie, by invitation of the late Dr. Leaming of New York, examined with him the diseases of the chest in his service at St. Luke's Hospital. One hospital case was given in full and many other from private practice, the autopsies in all cases verifying the diagnosis of pleuropericardial and diaphragmic adhesions. Dr. Goodwillie exhibited colored wax models showing these lesions. During the summer of 1878, by invitation of the Committee of the United States Government appointed to investigate bovine pleuropneumonia, Dr. Goodwillie with others made examination of condemned cattle. The autopsies were immediately performed, showing pathological conditions as found also in the human being.

Differential Diagnosis of Diseases of the Spinal Cord.—Dr. E. D. Fisher of New York said that this diagnosis rests entirely upon one's knowledge of the anatomy and physiology of the various parts of the cord. The anterior horns control the nutrition and action of the muscular system. Any destruction of this part must be followed by muscular paralysis and then wasting away. The lateral tracts have only motor functions, without any sensory or nutritional change. Hence disease here means only paralysis, but without any trophic signs. Since, however, cerebral inhibition is cut off there will be exaggerated reflexes, as seen in lateral sclerosis. The posterior tracts are entirely sensory. Hence in their lesions pain is prominent and other disturbances of sensation and later of coordination, which depends on feeling. Locomotor ataxia is the best example. Diseases classified according to the site of their lesions are in the anterior horns—poliomyelitis, acute and chronic, progressive muscular atrophy, and hemorrhage into the cord substance. All these present paralyses followed by atrophies. In the lateral or crossed pyramidal

tracts there will be lateral sclerosis following myelitis, injury and Pott's disease, all with pure paralyses and no atrophies. In the posterior columns there will be present all grades, degrees and variations of sensory disturbance and coordination making the symptom-complex of tabes dorsalis.

Pus in the Peritoneal Cavity.—Dr. R. T. Morris of New York said that leucocytosis is our guide to what is going on in the abdomen and should always be considered as an element of the treatment. Personal resistance by the patient is also a factor. Gauze drains are apt to increase shock by irritating the sympathetic nerve-filaments. Iodine poisoning from gauze may be mistaken for septicemia. Dr. Boldt of New York said that true septicemia is always fatal. Dr. W. G. MacDonald of Albany said that irrigation and drainage cannot be ignored and that the phenomena of no leucocytosis in virulent cases shows that blood count may not help at all.

Spinal Cocainization.—Dr. G. R. Fowler of Brooklyn discussed the indications and limitations of spinal cocainization in surgery. Whenever mental shock from consciousness of the circumstances about the operation and inconvenience from active reflexes are not to be feared, it is a very good substitute for general anesthesia. He has had 104 cases distributed upon foot, leg, knee, thigh, groin, pelvis and its contents, abdomen and thorax. Above the umbilicus this method is very unreliable in degree and duration. The extremities show effect the longest. In brief therefore its best fields are below Poupart's ligament.

SECOND DAY—JANUARY 30.

MORNING SESSION.

After attendance upon an interesting exhibition clinic at the Albany Hospital, the Society listened to a poem entitled Appendicitis by Dr. J. H. Doughty of Matteawan.

On Tendinitis and Tendovaginitis Prolifera Calcarea, with Roentgen-ray Demonstrations.—Dr. Carl Beck of New York read the following history: The patient, a Russian tailor, forty-two years of age, noticed a painless swelling formed at the dorsal surface of his right hand. In September, 1900, the growth had gradually reached the size of a moderately large apple. Osteosarcoma was suspected first, but the Roentgen-rays showed the presence of a chronic inflammatory process and a defect in the third metacarpus. Extirpation revealed a yellow, cheesy mass, filling the bone-defect. The synovia was also partially destroyed. But the most surprising feature of the condition was that the extensor tendons of the fingers, excepting the thumb, appeared as if cemented into one mass of mortar. By dividing this mass the knife gave a loud grating sound. Of the tendon of the third finger only a few rudimentary fasciculi had remained, so that it had to be sacrificed entirely. The fasciculi of the second and fourth extensor tendons were kept apart by the concretions. They were in fact so much incrusted that only a small portion could be left. The weight of the whole amount of the calcareous mass removed proved to be eighty grams. The microscopical examination, which was made by Dr. Henry T. Brooks, showed round-cell granulations and the presence of staphylococci, but no evidence of tubercule bacilli. There were also deposits of phosphates and carbonates of lime. The fragments of the tendons showed granulation of the peri- and interfascicular connective tissue. Hematoxylin colorized the degenerated tissue dark-brown violet and picrocarmin changed it into red.

Treatment of Puerperal Fever.—This was the title of a paper read by Dr. H. J. Boldt of New York. Its varieties are: Acute bacteremia, chronic bacteremia, sapremia, and septic infection; subdivisions may be made from the latter. He thought these terms better than septicemia and pyemia, and the term septicinfection used in the broad sense for infection. Acute bacteremia is caused by micro-organisms invading the circulatory system from some primary seat, the infection-producing elements multiplying so rapidly that the patient usually succumbs within five to seven days after the beginning of the disease. Usually the germs are streptococcus pyogenes; other pathogenic germs may be present.

Chronic bacteremia is caused by the invasion by streptococcus pyogenes alone or in conjunction with other germs, but they disseminate from an infected thrombus; they are not diffused in one large quantity, neither are they possessed of the same virulence. The production of abscesses in this condition, upon which the pathological difference between acute and chronic bacteremia depends, is due to organisms finding a resting-place outside of the blood-circulation, and there giving rise to abscess. All these diseases being due to "septic infection" in a *broad sense*, he would limit the application of this term to those cases in which the infection is local, bearing in mind that a local infection may have severe constitutional symptoms.

Sapremia is caused by the absorption of decomposition products, toxins, saprophytes; as for example, placenta, decidua, blood or lochia in the genital tract. This disease may develop into one of those previously spoken of. In many instances it is impossible to classify a case until the patient has been under observation for some time. Septic infection, although it covers all these varieties in a clinical sense, and is an appropriate term at the bedside, should not be used in reporting cases, without such details as will convey an idea of the patient's condition. The prognosis of acute bacteremia is unfavorable. He had seen no recoveries from it.

Prophylaxis is most important with puerperal women. Fever having developed, keep the patient at perfect rest. Next, attention should be directed to the primary entrance of the fever-producing agents. If the seat of infection is about the vulva or in the vagina, or both, the treatment

should be cleanliness. If no local injury is found, then the interior of the uterus may be examined. It should not be done if the general condition, especially the pulse, is good, and the temperature is not above 101° or 102° F., because retained tissue is usually expelled spontaneously in a short time. Therefore, unless it is known that foreign elements are within the uterus, it should not be explored, unless it seems to be necessary. Abstain from unnecessary meddling. For the removal of foreign elements a curette should be discarded, except by those accustomed to its use in such cases, and then only if the retained tissue has been located by the finger and cannot be removed by it. A curette should never be used in septic endometritis, because it intensifies infection by causing fresh wounds. An intra-uterine douche is always advisable before and after manipulations within the uterus. It should not be repeated unless the secretions are purulent, and there is a continued fever. Under such circumstances he had seen benefit result from an intra-uterine douche of peroxide of hydrogen, 25 to 75 per cent., or other antiseptic. He had found that if no intense systemic infection were present and if the uterus remained enlarged and relaxed, after being cleansed, a treatment of benefit is gentle massage of the organ at intervals varying from one to three hours. So far as he knew, this had not been advocated by any one previously. The massage is the same as when used for inciting uterine contractions for expulsion of the placenta—a circular motion. Antipyretics, especially the coal-tar preparations, are harmful; they lower the temperature only temporarily, and act with deleterious effect on the heart and nervous system. He had seen no benefit from gauze placed in the uterus for the sole purpose of drainage. If the infection is localized in the pelvic cellular tissue, or the peritoneum, the application of an ice-bag or coil should be resorted to. He had also found benefit from unguentum Credé. If there is positive evidence of pus, the abscess should be incised; the incision should be large to permit thorough cleaning and drainage. Frequently puerperal pyosalpinx is of gonorrheal origin. The safest treatment is vaginal incision. The patient should be handled carefully, so that adhesions in the pelvis are not disturbed. If patients with septic infection are not benefited by the treatment suggested, or if there is reason to believe that additional resort to minor interventions would be useless, and if we are sure that the continuance of infection comes from the uterus alone, hysterectomy should be considered. Serum treatment, as now in use, is of no benefit. In some instances of diffuse septic peritonitis, where there is no bulging from an exudate in the pelvis, an extensive abdominal section, separation of adhesions, with thorough flushing of the abdominal cavity with saline solution, and drainage, may be resorted to.

He has seen no benefit from saline infusions, and had no treatment to suggest for acute bacteremia. He does not believe that benefit is to be derived from incising the cul-de-sac of Douglas, and draining the pelvis with gauze for the purpose of aborting acute bacteremia, when there is no exudate in the pelvis. Chronic bacteremia should be treated according to indications in an individual case.

Early Diagnosis of Insanity.—Dr. Carlos F. MacDonald of New York said that this subject is important because usually the responsibility of recognizing insanity in the first instance devolves on the family physician. It is important also because insanity is a disease from which no one can claim exemption; and because it is more frequent, serious and far-reaching and involves a wider range of interests regarding the welfare and happiness of individuals, of families or of communities than any other malady known. There are about 22,000 insane in custody in this State today, involving an outlay of $20,000,000, for hospital plants, and of $5,000,000 annually for maintenance. There is no disease which creates a greater distress and helplessness on its invasion of the family circle, nor is there one more likely to be mismanaged in the initial stages. In their stress and anxiety the friends of the patient naturally turn to the family physician for advice and assistance. Hence the importance of informing oneself respecting its early symptoms. Its study presents nothing new or incomprehensible. Its phenomena on the mental side consist largely of modifications of the natural characteristics of the individual, whether in exaggeration, perversion or diminution. These modifications are merely the outward expression of disturbance of the intellectual areas of the brain. These symptoms may be summarized as a prolonged departure from the methods of thinking, feeling and acting which were usual to the individual when in mental health. Insanity is a comparative state, there being no common standard of sanity departure from which constitutes insanity. Every individual has his own standard, and in determining one's mental condition he must be compared with himself, *i. e.*, with his normal mental status, and not with any other man's. Therefore it is only when a man differs from himself, so to speak, that he may be regarded as insane. Two individuals may exhibit precisely similar symptoms and the one be sound and the other a lunatic. The invasion may occupy days, weeks or even months, although in some cases the onset is quite rapid and any marked change in the mental or moral tone of an individual should at once arouse suspicion. Prominent prodromata are disturbances of bodily functions, morbid emotional manifestations and alterations in the mental characteristics. Somatic functional disturbances express themselves in various ways, such as *pavor nocturnus*, insomnia, headache, tinnitus vertigo, vasomotor disturbances, anorexia, indigestion, constipation, etc. Any or all of these symptoms may occur in persons who never become insane; hence, while frequently observed in the prodromal stage of insanity, they are not pathognomonic. When found, however, they are always significant, especially in persons

predisposed to mental disease. Insanity is rarely due to a single predisposing or a single exciting cause. Usually a combination of causes will be found. Although the immediate cause is malnutrition of the brain, any disease or condition which impairs the bodily nutrition or alters unfavorably the quality or quantity of the blood-supply is capable of becoming a cause of insanity. The function of the mental faculties depends on the health of the physical system. There can be no unsoundness of mind, in a medical sense, without unsoundness (disease) of body. Many cases of acute insanity could be avoided if the prodromata were recognized and relieved. Prevention is better than cure, and to recognize mental disorder in its incipiency will frequently enable remedial measures to be adopted most opportunely for arresting its progress. Doubtless many minds of the highest order have been damaged beyond repair simply for want of appropriate treatment during the early manifestations of their disturbance.

Dr. Drayton of New York said that the timely elucidation of this important matter was serviceable to the Society, because the early and careful diagnosis of insanity was annually more important and, though not easy, should be more commonly within the ability of the average practitioner.

Contribution to Pelvic Infection in Women.—Dr. C. A. L. Reed of Cincinnati, President of the American Medical Association, guest of the Society, drew the following conclusions: The barriers to infection are (1) the epithelium in the genito-urinary tract; (2) the anatomy of the cervix uteri and the characters of its secretion; (3) the vagina and specifically its acid secretion; (4) the gonococcus is especially deadly to the epithelium; (5) the bacteria non-pathogenic or mildly so in one section may be virulent elsewhere; (6) in ways not yet known the phagocytes protect; (7) septicemia in serious or deadly form results from infection when the genus or their toxins circulate in the blood.

Dr. Boldt of New York said that the resistance and constitution of the patient are also barriers to infection in unknown ways. Dr. Dudley of New York said the gonococcus always leaves its mark in scars about the small gland-ducts of the vulva, vagina and urethra, and when he sees such scars he always is sure of local infection in the past.

The Society here passed a resolution to support the Pathological Institute of the New York State Hospitals for Insanity and Related Diseases in its fight for existence before the present Legislature.

The Anniversary Address.—Dr. A. M. Phelps of New York presented the Radical Cure of Inguinal Hernia as the subject of the ninety-fifth presidential address. He said that there is probably no other surgical affection which has commanded more attention from the profession, or wrought more disaster to the human family, than inguinal hernia. When it is remembered that for hundreds of years no rational operation had been attempted for the relief of strangulated hernia; and, knowing full well the frequency of that dangerous malady and the frightful mortality, amounting to more than seventy-five per cent. when not treated surgically—we can fully appreciate the importance of preventing the occurrence of strangulated hernia by a rational operation before strangulation takes place.

For more than two thousand years, surgeons of every decade and century have proposed and performed operations based upon some theory or other to prevent the descent of the intestine into the inguinal canal, always meeting with a signal failure; and it may seem strange, but still it is true, that not until twelve years ago was any operation performed that would receive one moment's consideration to-day from any surgeon who is familiar with the subject.

Up to 1846 cauterization, ligation of the sac and spermatic cord subcutaneously, suturing of the canal and the sac either subcutaneously or through an open wound, excision of the whole or part of the sac, castration together with the actual cautery applied to produce sloughing of the parts, are vividly described.

Another favorite method was the introduction of foreign bodies into the hernial sac, the object being to produce a mass of new inflammatory material, which would prevent the descent of the intestine. The injection of irritating fluids within or outside of the hernial sac became a favorite method. But of all the methods of mediæval times, the one that has survived is subcutaneous suture, which has been practised almost up to the present time in Great Britain and Italy. The Bassini operation appeared in 1888 and that of Halsted in 1889.

Technic.—The operation first performed by Dr. Phelps in the winter of 1892-93, with the modifications he has made, is as follows: An incision is made from a point one inch to the inner side of the anterior superior spinous process to the spine of the pubis, and carried down to the sac and to the peritoneum, splitting the entire length of the inguinal canal to about an inch and a half beyond the internal ring. The cord is separated from the sac and lifted from the canal, and the sac cut away. The sac is not cut too short, neither is it left redundant. This sac is stitched up with a continued suture of fine silver wire. The transversalis muscle and the internal oblique are separated from the external oblique and stitched together with a continued suture of wire, beginning at the spine of the pubis, closing the canal firmly. The muscles are slightly notched external to the internal abdominal ring to allow the cord to pass through without pressure. The third row of sutures closes the aponeurosis of the external oblique, together with the pillars of the ring the entire length of the wound, the aponeurosis being notched at the point where the cord makes its exit. Over all, the skin and cellular layer are stitched with catgut. Great care is exercised in stopping all hemorrhage before the wound is closed. After the sac has been stitched up (and underneath all of the muscles) over the entire length of the inguinal canal is placed a fine filigree

of silver wire. Over this each muscular layer is stitched. The muscles must be perfectly separated one from the other, in order to secure the best coaptation. The skin is stitched with catgut. The cord lies directly under the skin, as in Halsted's operation. In a very fat subject, a small drainage tube is inserted down to the wire, which is removed at the end of thirty-six hours. Three rows of continued wire sutures are used in all herniæ, *viz.*, neck of sack, deep layer of muscles and external oblique. In cases of small hernia, instead of putting in the wire filigree or mattress, a few loops of wire are placed directly across the canal over the transversalis fascia and peritoneum, and the muscles stitched over it; or the layers of muscles are closed with a continued suture of fine silver wire, both ends of which are anchored, and all of the ends cut short so as not to irritate the tissues. For large openings a wire mattress or filigree is absolutely necessary. In all cases of relapsed herniæ, when there is atrophy of muscles due to pressure, it is imperatively demanded or a relapse will likely occur. In smaller herniæ a few wire loops are sufficient; a mattress suture, the two ends of which are fastened firmly in the muscles, is all that is required, the mattress being omitted. Two rows of these continued sutures are necessary, one for the deep and the other for the superficial layer of muscles. In making these filigrees from ten to a hundred and fifty feet of wire are required, depending on the size of the opening to be closed. It has been urged that this wire will cause suppuration. Suppuration is not produced by any foreign body. It is always produced by bacteria. He has never yet been obliged to remove the wire, with the exception of once or twice, and these were soon after operation on account of certain complications arising not due to the wire. Out of 238 cases thus treated he has had no deaths and but eighteen suppurations. None of these suppurations destroyed the result of the operation and all were due to causes proved not to depend on the wire.

WEDNESDAY—AFTERNOON SESSION.

A Hair-Cast of the Stomach; its Successful Removal by Laparotomy.—Dr. N. Jacobson of Syracuse read this paper. He showed the cast which weighed fifteen ounces. Dr. R. T. Morris of New York City said he had once found hair in the appendix.

Surgery of the Spleen.—Dr. J. C. Warren of Boston said that the diseases for which this viscus is amenable to operation are as follows: Malarial spleen, anemia, leucocythemia, chronic enlargement, actual hypertrophy, atrophy of the liver with secondary splenic enlargement, amyloid degeneration, ecchinococcus cyst, angioma, fibroma, abscess, rupture, tuberculosis, sarcoma, floating spleen, twist of the pedicle. The revised death-rate for such cases is 12.2 per cent.

Dr. Van der Veer of Albany said that he operated on what proved to be an angioma of the spleen. The patient lived in fair health with a chronic sinus for fourteen months and died eighteen months after operation.

Inguinal Hernia.—Dr. M. Ricketts of Cincinnati gave a complete and comprehensive description of the anatomy involved in inguinal hernia. He claims that, etymologically and anatomically, the use of the word canal is wrong, ring being the proper word. A circular letter was sent to over one hundred prominent surgeons. Many interesting facts can be deduced from the replies received. Thirty-four surgeons gave an approximate percentage of recurrence in their practice; this percentage varies from one to fifteen per cent.; this last percentage agrees with that of Professor Girard of Berne for results in Europe. The average is 5.58 per cent. based on 6027 operations by 34 surgeons. From statements contained in letters received in answer to the circular, it is fair to infer that only one-half of the total number of operations were reported. This would bring the percentage up to about 15 per cent. These letters show that infection and recurrence are less frequent when wire or silkwormgut is used in the Phelps, Halsted, or Abbe method of operation. The writer bears unequivocal testimony to the success of the Phelps operation; he employs it and considers it ideal. It is the only one that insures successful and permanent cure. He agrees with Abbe that silver wire or silkwormgut is to be employed in preference to absorbable sutures. He does not believe that suppuration has anything to do with causing recurrence; the real cause or rather causes of relapse are deficient origin (attachment) of the internal oblique muscle, pressure of a truss (where one has been worn), length of time that hernia has existed, lack of nerve and blood-supply, and intra-abdominal pressure rupturing the cicatrix. The last factor can be disregarded if the Phelps method is employed, because if the wire mattress is once placed properly there is no possibility of relapse by a rupture from the intra-abdominal pressure. He doubts the doctrine that varicocele is a cause of inguinal hernia, and holds that all herniotomies should be regarded as modified laparotomies. The prevalence of hernia suggests the questions. Is there anything in the habits engendered by our rapidly-advancing civilization that is conducive to the production of hernia? Is man progressing toward morphological perfection or degeneration? He refers to the historically interesting edict of Constantine, forbidding operations which involve loss of cord and testicle, for fear that the population of the country would suffer.

Grastro-jejunostomy in Gastrectasis.—Dr. A. H. Cordier of Kansas City, Mo., pleaded for this operation in preference to the radical measures when such can promise very little or no relief and when they involve undue hazard.

Toxin of the Colon Bacillus.—Dr. V. C. Vaughn of Ann Arbor, Mich., said that the colon bacillus appears to make a poison insoluble except in the body fluids. This explains why in some body fluids it is innocuous and in others very fatal.

The So-Called Traumatic Neuroses.—Dr. H. N. Moyer of Chicago, Ill., denies the existence of this condition and says the symptom-complex called by this name is either hysteria, neurasthenia, hypochondria or melancholia.

The Election of Officers.—The Nominating Committee reported the following named gentlemen as officers for the ensuing year: Dr. H. L. Elsner of Syracuse, President; Dr. L. N. Lanehart of Hempstead, Vice-President; Dr. F. C. Curtis of Albany, Secretary; Dr. O. D. Ball of Albany, Treasurer.

These gentlemen were duly elected and the meeting adjourned on Thursday morning.

BOOK REVIEWS.

Report of the Surgeon-General of the United States Navy, for the Year 1899; Washington, D. C. 1900.

Candor makes necessary the statement that some of the numerous bureau reports that go out of the government printing office in Washington are models of dryness, replete from cover to cover with uninteresting details, made up mostly after the manner of the reports of some of the great State Hospitals for the Insane in the State of New York. But this statement is untrue, in so far as it applies to the report of Dr. W. K. Van Reypen, Surgeon-General of the United States Navy.

Dr. Van Reypen's report is a model of completeness and compactness, and contains a vast amount of general and special information, information that is was possible to procure and present only on account of the recent war with Spain. Indeed, the very first page of the report contains a statement that almost takes one's breath away, judging from the way that public expenditures are made these days. Dr. Van Reypen says "$100,000 was appropriated by Congress for the Bureau of Medicine and Surgery for war purposes, and $37,000 of this has been returned to the Treasury." Think of it! Marvelous, indeed, that a great bureau of the government should permit, nay, cause this amount to lapse back into the Treasury as an unexpended balance. There is no need in dwelling on the why and wherefore of this balance; it is there, and that suffices.

Dr. Van Reypen calls attention, as many of his predecessors in office have done before, to the great demand for more medical officers in the Navy. There has been an urgent need for an addition to this force for many years, and there has likewise been a demand for raising the grade of the junior officers in the medical corps. Not only are these junior officers underpaid and have a lower relative rank than men of virtually the same standing and grade of education in the Army; but they do not receive the same emolument from the government; which facts tend to make a medical position in the Navy less desirable than in the Army. The result is obvious; the Army selects its men from a long waiting list; the Navy is rather forced to accept, not inferior men; but to suffer great delay in procuring the number of men it actually requires.

In speaking of the work of the medical officers, Dr. Van Reypen has this to say on this point: "An examination of the professional work of the medical officers, ashore and afloat, exhibits care and accuracy in the preparation of all official papers and a commendable zeal in the performance of their duties." The Surgeon-General states that the daily average number of patients under his care during the year was 678.63; the total number of men on duty daily in the Navy being 23,986. There were 173 deaths reported during the year, of which number 118 were from disease and 55 from injuries. The low number from injuries speaks volumes for American seamanship and all allied forces, when we remember the great historic battles that were fought in Manila Bay and at Santiago.

The report is complete with histories of cases written by the officers of the Surgeon-General's corps. Some of the cases are extremely interesting and will find a lasting place in medical literature. And when we remember how these medical men did their work, how they operated under such great disadvantages as they often did, we marvel at the success they so frequently attained. It seems that the day is not far distant when the location and care of the "sick bay" on most ships will receive more consideration at the hands of those who design and construct these ships than they do at the present time. Think of a man lying in bed with a fractured leg and having that leg refractured just as it has commenced to knit together, simply from the concussion of the firing of a great gun within a few feet of that man's bed! This is not even humane, and such crude facilities for caring for the sick should be abolished just as rapidly and as effectively as possible.

If the Surgeon-General will permit the suggestion, we believe it would be an excellent investment for him to send his reports broadcast throughout the country, or as far as he may be able, in order that physicians of influence may become better acquainted with the actual medical and surgical work done in the navy. These physicians might then take an interest in it and might be able to secure the interests of the representative in Congress from their district. Eventually good will come of this, by virtue of the Surgeon-General of the Navy and his officers getting more of what their service requires. On the whole, we have nothing but praise for Dr. Van Reypen's report. It is a document well worth reading, worth filing and preserving, and is a valuable addition to any library.

Modern Medicine. By Julius L. Salinger, M.D., and Frederick J. Kalteyer, M.D. W. B. Saunders & Company, Philadelphia and London.

We have carefully gone over this volume of 801 pages in the hopes of finding something modern in it, but we regret to say that we find it distinctly

commonplace. The opening chapter on Symptomatology consists of a short account of the methods of examination. This is suggestive more of a quiz-compend than of a serious work on medicine, while Chapter II. on Clinical Bacteriology contains very little clinical knowledge whatever and should be designated descriptive bacteriology. The size and manner of growth of the various organisms is told, but what relationship, for instance, bacillus pyocyaneus has to clinical medicine is not given. The rest of the book is made up of an abridged account of the various diseases. It is sufficiently accurate to aid a student in passing examinations, but as a serious guide to the large subject of medicine, it should not be considered. The mechanical part of the book is all that could be desired.

Psychopathia Sexualis. With Especial Reference to Antipathic Sexual Instinct. A Medico-Forensic Study. By Dr. R. von Krafft-Ebing. Translation from Tenth German Edition. W. T. Keener & Co., Chicago.

The medical public is sufficiently cognizant of the value of this book and the English speaking public is to be congratulated on having an adequate translation. The previous one was more of a travesty than a serious performance. The present volume has preserved the truer point of view of the author.

The conditions here described are found in human nature, and as such are entitled to serious consideration and study. Such books are not written for babes and sucklings, and it is to be regretted that the historical form was adopted by the gifted author of the original, but there probably was no other way of presenting the subject.

The publishers' part in this volume is excellent.

Encyclopedia Medica. Under general editorship of Chalmers Watson, M.B., M.R.C.P.E. Vol. II. Brachial Plexus to Digestion; Vol. III. Diphtheria to Food; Vol. IV. Foot to Hernia. Longmans, Green, & Co., New York.

We have had occasion in reviewing the first volume of this large enterprise to speak of its excellent character. In the succeeding volumes, three of which are before us, the impression is made more distinct and, furthermore, the practical character of the work is made more and more evident with each new volume. As stated in our earlier review the Encyclopedia Britannica seems to have been the model on which the present work is constructed. This has its advantages, as well as its defects, thus the more typically medical topics are discussed while information bearing on collateral branches is absent. The chief weight is laid on medicine and surgery. Anatomy and physiology are well represented, hygiene and general topics as well, but materia medica, as such, is conspicuous by its absence. Thus, the drugs digitalis, ergot, belladonna, etc., are not even mentioned.

In Volume II. the article on the brain is very well done. There is not too much of it and yet what there is, is distinctly modern and authentic. The articles on diet, climate, digestion and metabolism are conservative and practical. In Volume III. the discussions on diphtheria, diseases of the ear, eczema, the enzymes and the development of the fetus are especially interesting and complete.

Volume IV. contains some excellent descriptions of diseases of the gall-bladder and the gastro-intestinal diseases of infancy. The chapter on gout is especially noteworthy, as is also the discussion of the physiology of the heart and its diseases. The cardiac neuroses are treated at some length.

These volumes are illustrated more fully than was Volume I. and already it may be said that the series is destined to become a very valuable one for handy reference. The valuable features are the concise and authentic descriptions and the full discussions of treatment.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Food and the Principles of Dietetics. By Dr. Robert Hutchinson. 8vo, 548 pages. Illustrated. William Wood & Company, New York.

Sanity of Mind. A Study of its Conditions, and of the means to its Development and Preservation. By Dr. David F. Lincoln. 12mo, 177 pages. G. P. Putnam's Sons, New York and London.

Enteroclysis, Hypodermoclysis and Infusion. A Manual for Physicians and Students. By Dr. R. C. Kemp. 8vo, 349 pages. Illustrated. Jas. T. Dougherty, New York.

Studies from the Department of Pathology of the College of Physicians and Surgeons, Columbia University, New York. Vol. VII., for the year 1899-1900.

Cancer of the Stomach. A Clinical Study. By Dr. William Osler and Thomas McCrae. 8vo, 158 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Diseases of the Nervous System. A Text-Book for Students and Practitioners of Medicine. By Dr. H. Oppenheimer. Translation from Second German Edition by Dr. Edward E. Mayer. 8vo, 900 pages. Illustrated. J. B. Lippincott Company, Philadelphia and London.

A Manual of Medicine. Edited by W. H. Allchin. Vol. II. General Diseases. Demi 8vo, 380 pages. Illustrated. The Macmillan Company, London and New York.

The Care of the Consumptive. By Dr. Charles Fox Gardiner. 12mo, 182 pages. G. P. Putnam's Sons, New York and London.

A Text-Book of Pharmacology and Therapeutics. Or the Action of Drugs in Health and Disease. By Dr. Arthur R. Cushny. Second Edition, Revised and Enlarged. 8vo, 732 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York.

Panama and the Sierras. A Doctor's Wander Days. By Dr. G. Frank Lydston. 8vo, 283 pages. Illustrated. The Riverton Press, Chicago.

Rudiments of Modern Medical Electricity. By Dr S. H. Monell. 12mo, 165 pages. Illustrated. E. R. Pelton, New York.

ORIGINAL ARTICLES.

SOME UNUSUAL CASES OF INFECTIOUS DISEASES —A CLINICAL REPORT.

BY DELANCEY ROCHESTER, M.D.,
OF BUFFALO;
ASSOCIATE PROFESSOR OF MEDICINE IN THE UNIVERSITY OF BUFFALO.

Case I.—George D., American, aged four years. December 19, 1899, I found the boy with a sore throat that had come on about midnight of the 18th. His pulse was 80, of good quality and rhythm; temperature, 100° F. His pharynx was red; he was not hoarse; he had slight rhinitis. I make a practice of taking a culture from every sore throat and did so in this case as a routine matter. I was surprised at the report, received on the morning of the 20th, of pure culture of the Klebs-Loeffler bacillus being found. I immediately gave him 2000 units of antitoxin, although there was no exudate visible and the constitutional disturbance was no greater than the day before. Twelve hours after the administration of the antitoxin he discharged two large pieces of membrane from his nose. Twenty-four hours later he appeared better, but thirty-six hours later—that is, on the morning of the 22d—both tonsils and the posterior wall of the pharynx were covered with membranous exudate and there was a rise of temperature to 101.5 F., and of pulse to 120. The child was given 1000 units more of antitoxin and Loeffler's solution applied to the exudate. In thirty-six hours the exudate had almost entirely disappeared, and in forty-eight hours the throat was clear, the temperature normal, the pulse 80 and of good quality. The diphtheria bacillus had disappeared by December 30th, eleven days after the onset.

Case II.—C. W., English by birth, female, trained nurse, was first seen by me March 14, 1900, complained of cough and a little sore throat. Temperature was 103° F., pulse 100. There was some hoarseness and she complained of a feeling of soreness under the sternum. The physical signs of general bronchitis were present. The pharynx was a little red and as a matter of precaution I took a culture. The report was pure culture of Klebs-Loeffler bacillus. She was given 2000 units of antitoxin on March 15th. Twenty-four hours later a slight exudate appeared on the left tonsil. The temperature remained high and the pulse frequent and she had the appearance of profound toxemia. The respirations also began to increase in frequency and the hoarseness was more marked. Headache was violent and restlessness and sleeplessness were present. Under the circumstances, fearing that the bronchitis was diphtheritic in character, I gave her 2500 units more on March 17th, and applied Loeffler's solution to the throat. After this there was slight improvement in her general condition for about twelve hours and then she became decidedly worse as far as her general symptoms were concerned, the throat improving in its appearance, although the slight exudate still persisted on the tonsil. She was given 2000 units more on March 18th. Thus in eighty hours she had received altogether 6,500 units of antitoxin. Twenty-four hours later her throat was clear of exudate, but her general symptoms persisted and physical examination of the chest revealed the general bronchitis still present and a decided consolidation of the lower lobe of the right lung. At the same time she began to expectorate more freely, the sputum having in a mild degree the physical characteristic of pneumonic sputum, but not quite as tenacious and more blood-streaked than rusty. Nevertheless, examination showed it to be swarming with the pneumococcus in pure culture. Nine days after her admittance to the hospital culture from her throat showed the disappearance of the diphtheria bacillus. On the afternoon of March 23d, the tenth day of illness, her temperature, which had ranged between 101° and 103° F., began to fall, reaching 99.8° F. at 10 a.m., but in the afternoon it rose again to 101.3° F., and remained between that point and 100° F. for twenty-four hours. At 10 p.m., March 25th, she vomited. From midnight her temperature began to rise steadily, so that by 6 p.m. of the 26th it was 103° F., pulse 120, and respiration 38. At the same time she complained of intense headache and there was pronounced twitching of the muscles in her sleep. On the 27th her temperature ranged between 100° and 102.5° F., and she began to cough severely and complained of some pain in limbs. On the 28th, being the fifteenth day of disease, her temperature, pulse and respiration rose steadily, reaching 104° F., 130 and 40 respectively. At the same time she complained of great pain and soreness of limbs and chest, pain on motion of joints, and broke out in a profuse, red, macular rash over her body and limbs, but not on face. After reaching 104° F. at 10 p.m., March 28th, her temperature, together with her pulse and respiration, began to fall and continued to do so, accompanied by profuse sweating, through the 29th and 30th, reaching 98° F., 84 and 24 respectively at 6 a.m. of the 31st.

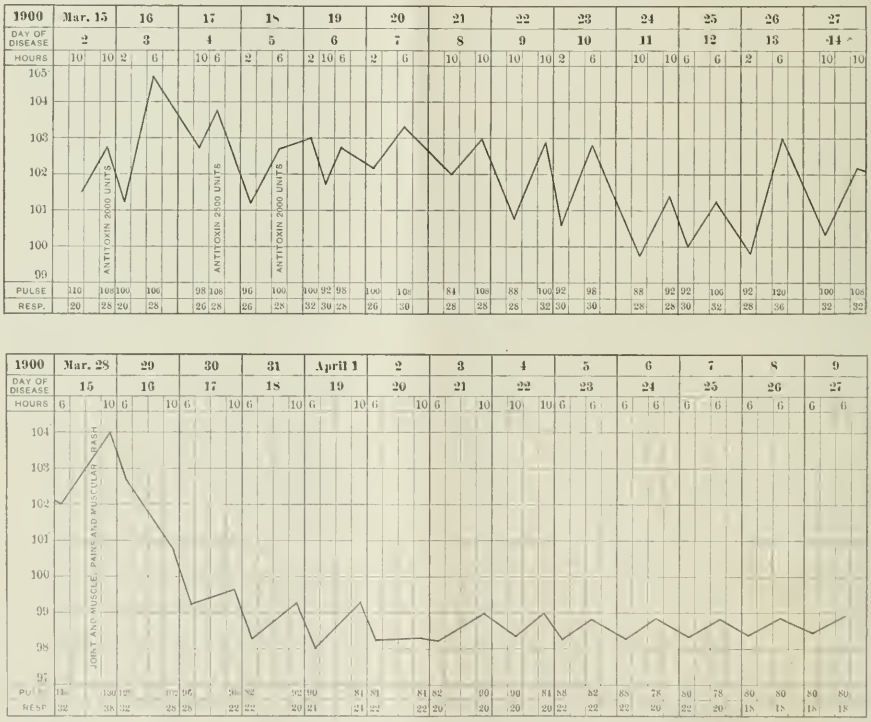
From that time on her convalescence was rapid and uninterrupted and she was discharged from the hospital April 9th, twenty-eight days after she was taken ill.

These two cases are interesting as showing the value of making cultures from all cases of sore throat. In this way, in each case I was able to make a positive diagnosis fully twenty-four or forty-eight hours earlier than could otherwise have been done. They also illustrate the value of large

doses of antitoxin given early, together with the local application of Loeffler's solution, in causing the early disappearance of the organism from the throat.

The second case illustrates the importance of the use of all methods of diagnosis and the possibility of synchronous infection by two virulent micro-organisms. If it had not been for the examination of the sputum we might have been justified in considering the bronchitis and the pneumonia as diphtheritic in origin and might have continued giving even larger doses of antitoxin.

Case III.—November 8th, 1899, I was called to see J. L., aged eight years. The little boy had come home from school, complained of feeling sick, had vomited, and when I saw him was complaining of headache. His temperature was 102.5° F., his pulse 120, respiration 28. I immediately asked his mother whether there was any scarlet fever in the neighborhood. She said no. On examining him further I found a marked bronchitis with a few patches of pneumonic involvement at the base of both lungs. I gave the boy calomel, cupped his chest and ordered hot mustard foot-



Temperature Chart in Case II.

The urine remained normal, except for slight diminution in amount of chlorides, thus showing the possibility of an individual suffering from two violent infections without the production of albuminuria.

The joint and muscle pains, the high rise in temperature, pulse and respiration of the last two days before the crisis, and the appearance of the rash, I think, were probably due to the antitoxin —the real crisis having started in three days before.

The three following cases of scarlatina *sine eruptione* are interesting:

baths every two hours. The next morning the nurse called my attention to the fact that during the footbaths he became very red, but when I saw him there was no rash on his body, and his tongue and throat showed no evidences of scarlet fever. In five days he was feeling very well and in eight days I had discharged him.

Cases IV and V.—On November 18th I was called to see his two little sisters, both of whom were fretting and a little feverish, with a temperature of 99.5° and 100° F. respectively. Their throats were not sore, but there was a little peculiar mottling of the skin, and they both had vom-

ited. The following day I was out of town and Dr. I. M. Snow went to see them in my absence and said that he thought they might both be mild cases of rötheln. In none of the three cases was there any albuminuria. Eighteen days after the little boy was taken sick he was so well that I vaccinated both him and his brother. When I had finished with him, however, I noticed that his fingers were desquamating a little, and I said to his mother, "I wonder whether we have had some mild cases of scarlet fever here." This doubt was settled by the oldest boy coming down in a few days with a typical case.

The following is the most remarkable case that I have to report:

Case VI.—J. Q., male, aged five years, entered the Buffalo General Hospital December 17, 1899, with the history of exposure to a case of scarlet fever during the stage of desquamation the week previous. The day before entering he suffered from nausea and vomiting, followed by fever and a slight punctate rash. His case was diagnosed as scarlet fever by Dr. George Himmelsbach, a physician of large experience in both hospital and private practice, and he was sent by him to the hospital. During the time that he was there under my observation the rash persisted eight days, his tongue was red and showed the papillæ prominently, his throat was slightly sore, his tonsils were swollen, but showed no exudate; the cervical glands and neighboring connective tissue of neck were swollen. He had a faint trace of albumin in urine, but no casts.

December 25th he began to desquamate and this continued until January 10, 1900. About January 6th another case of scarlet fever of very severe type, with an eruption almost vesicular in character, was placed in the same room with the convalescent. On January 12th I ordered that the first boy have his disinfectant bath and be discharged the next day, but when I made my visit on January 13th I found that he had a sore throat and that his temperature had risen to 101.8° F. The following day his temperature had risen to 104° F., and he was covered with a bright, coarse rash, vesicular and punctate in character, his tongue was coated, but the edges were decidedly red and the tip showing the elevated papillæ. He had headache and slight delirium. On January 16th he developed an acute nephritis of marked degree. In fact, he went through a second attack of scarlet fever of a severe type, desquamating freely. He was discharged from the hospital February 15, 1900. During the primary attack he was seen by Dr. Himmelsbach, who sent him into the hospital, by Dr. McCarthy, who was the interne in charge of the contagious wards, and by me. There was no doubt as to the correctness of the diagnosis. During the second attack he was seen by the three who had seen him in the first attack and by Drs. Stockton and Wende. There was again no doubt as to the correctness of the diagnosis. So far as I know, this case is unique in the fact of its recurrence only three days after the completion of the desquamation of the first attack.

REMARKS UPON THE CONSTRUCTION OF AMPUTATION-STUMPS, WITH A REPORT OF TWO CASES OF AMPUTATION BY THE OSTEOPLASTIC METHOD OF BIER.[1]

By ALEXIS V. MOSCHCOWITZ, M. D.,
OF NEW YORK;
ADJUNCT ATTENDING SURGEON TO THE MT. SINAI HOSPITAL.

THE ablation of an extremity for irremediable injury or incurable disease is so self-apparent that, without going too far back into the history of surgery, it may be safely assumed that it is one of the oldest operations recorded. The obvious simplicity of the procedure would lead us to believe that, with advancing centuries, its operative technic should have been perfected to such a degree that but very little of value could be added to this time-honored chapter of surgery. And yet a scrutinizing investigation of the subject will readily demonstrate the fact that our technic, especially when viewed in its final results, is anything but perfect. Everybody who has had occasion to follow up closely the ultimate fate of amputation stumps will agree with me that there still remains considerable to be desired. The proof of this is evident, in that most surgical text books very properly devote at least one, if not many, chapters to the discussion of the diseases of amputation-stumps and their treatment.

Critically examined, every amputation-stump should respond to the following requirements: (1) It must be able to support the weight of the body. (2) It must be painless. (3) It must be no more liable to local disease than any other portion of the body. (4) It must disfigure its owner as little as is commensurate with the nature of the ailment. It is needless to add that the first requirement does not pertain to stumps of the upper extremity.

It is far from me to deny the existence of stumps which respond to all the requirements mentioned; on the contrary, there are many quite well known, but if these are carefully examined it will be very readily seen that they are either typical exarticulations or that they belong to either the Pirogoff, or Gritti, or Sabanjeff type—in other words, in proximity to a joint, a kind of modified exarticulation, while amputations through the diaphysis will not stand the test.[2] Nor can it be denied that there are quite a number of people who can walk very well even after an amputation through the diaphysis; but in the greatest majority of these cases thanks is due not so much to the skill of the amputating surgeon, but more to the exceptional skilfulness of the manufacturers of artificial protheses. In spite of this fact, it does not follow that surgery is absolved from all further attempts at improving the operative technic to

[1] Read before the Surgical Section of the New York Academy of Medicine, Nov. 12, 1900.
From the First Surgical Division, Mt. Sinai Hospital; Arpad G. Gerster, M.D., Attending Surgeon.

[2] Of late Hirsch has published in the *Archiv für klinische Chirurgie*, Band LXI., Heft 3, excellent results obtained by long-continued after-treatment with massage, and active and passive motions; this method is certainly very much in place, when for some reason or other we are compelled to amputate by the older methods.

such a degree that all stumps should be in a condition to fulfil the imposed requirements. That ability to wear a skilfully-manufactured artificial leg is alone not a desideratum will be acceded to if the following points are taken into consideration. Artificial legs, as a rule, are compelled to take their support from some point, or points, higher up; in the leg from the head of the tibia and fibula, and in the thigh from the os innominatum, while the stump proper merely hangs loose in a voluminous socket and in reality is used merely

Fig. 1.—Case of Alex. T., osteoplastic amputation of leg.

for propelling the artificial leg and not at all for the support of the body. Another point, while apparently a subordinate one from the surgeon's standpoint, is nevertheless a most important one from the patient's point of view, and this is the perhaps exorbitant cost of a well-made artificial leg. The natural outcome is that we see many of the poorer classes who, because of a stump which cannot give them direct support, or the inability to pay for an artificial leg, are compelled to hobble around on crutches, while if the stump were properly made, these people would with a comparatively cheap "peg leg" become useful to themselves and to the community.

Among those surgeons who readily appreciate the importance which a good supporting stump is to its owner there arose the natural consequence that more of an extremity was sacrificed than was absolutely indicated by the nature of the ailment; this was gained by exarticulations at the joint higher up and also gave rise to the term "amputation at the seat of election;" for instance, upon the leg in its upper third. I believe, with the method to be shortly described, the term will become either obsolete, or will be reserved for those cases in which rapidity in the course of the operation, for manifold reasons, is urgently indicated, as it is undeniable that the formation of a stump by Bier's method will even in the most experienced hands consume a somewhat longer time than the simple amputation by the older methods. In a word, every place above the seat of the disease is a place of election by Bier's method.

It would carry me far beyond the limits of this short communication if I were to attempt to describe or even mention the various improvements and course of evolution in the operative technic of amputation; but, if we admit that the usefulness of a stump and its physiological function are the objects to be aimed at, we must also admit that the most important advance in the technic of amputation is to be credited to the ingenuity of Pirogoff, because it gave an impetus to the subsequent development of other methods; these, like the amputation of Gritti, or the more recent ones of Sabanjeff, Abraschanoff and Scymanofsky, are none the less good, but they are applicable only to special regions, as the knee-joint and elbow-joint; while the underlying principle in all of them is merely the one described by Pirogoff. Surgery appeared to have rested on its laurels and apparently accepted the ills supposedly inherent to amputation-stumps, until Bier developed a practically entirely novel method, applicable to any part of the extremities. Credit, however, is to be given to Bier not only for the introduction of this method, but also, and perhaps to a far greater degree, for the careful and deliberative studies and investigation upon the physiology and pathology of stumps in general, by which he has proven the fallacy of many hitherto faithfully accepted theories regarding amputation-stumps and has paved the way for a long series of modifications and improvements.

The theories hitherto accepted regarding the requirements, the presence of which is absolutely indicated in a stump designed with a view of perfect function, have been manifold, and, although it is undeniable that from a cosmetic point these stumps leave nothing to be desired, their usefulness was so meager that a revision and modification of these theories were not only in place, but were very much indicated. Bier and his collaborators have undertaken this work and, after a careful study and investigation of this subject, extending over ten years, have ably refuted the vari-

ous theories and left them without any scientific foundation.

1. For a while the volume and thickness of the stump were supposed to be the deciding factors, because it was found that stumps following amputations through the comparatively broader surfaces of the joint ends could stand the superposed pressure better than stumps through the diaphysis; but Bier has proven that this theory is not tenable. He has published cases in which the stumps were perfect in every respect, yet they were no broader than the diaphysis through which they were made, with the only difference that he has closed the medullary cavity by a small osteoplastic flap. On the other hand, everybody has seen stumps with broad bone surfaces (epiphyseal), which were unable to properly functionate, because a thin lamella of the articular surface was sawn off at the time of the operation.

2. A faulty interpretation of the stumps following amputations by the Pirogoff or Gritti method led to the adduction of the hypothesis that stumps gave a good functionating result only when covered by skin which is designed by Nature for exposure and pressure. In reality, we find this to be the case in Pirogoff's amputation, in which the skin covering the stump is taken from the thick skin of the heel, and in the Gritti amputation, in which the flap is formed out of the tough skin covering the patella and tuberosities of the tibia. But that this alone is not the deciding element in the good results of these methods is effectually proven by Bier, who had occasion to observe perfect function in stumps covered by other skin. In one of his cases an excellent stump was obtained, in spite of the fact that the skin flap was formed out of the very tender skin covering the tendo-Achillis. Bier has also shown that even the most tender skin becomes hypertrophied, so as to resemble the skin of the planta pedis, if exposed to use.

3. There are many other theories, too numerous to enlarge upon and all disproven. Of all accepted rules, about the only one to which Bier allows some importance is that the resulting scar must not lie directly over the exposed surface of the stump, although even this is not of sufficient importance to induce him to sacrifice an additional portion of the limb to obtain this result.

It is not at all easy to overthrow rules which have obtained a firm foothold, but it is a far more difficult task to replace them by a more perfect substitute. After a long series of experiments and, for that matter, also failures, Bier has solved this task in admirable fashion by his osteoplastic amputation method to be shortly described. No one who has had the opportunity to compare the two methods will deny the superiority of it. There remained only the proper interpretation of the excellent results obtained. The careful observation of his results has led Bier to lay down the following rule: *The perfect functionating of the stump depends almost exclusively upon the bone. The bone must not expose on its supporting surface a wound. It is therefore necessary to occlude the sawn surface with a periosteal bone flap. When this is impossible, it may be more proper to exarticulate.*"

In the preceding special stress was laid upon the good functional ability of the stump, and one may naturally ask how far the necessity arises for similar more or less complicated methods in amputations upon the upper extremity, or upon the toes and fingers. This question in the opinion of the writer should be replied to emphatically in the *affirmative*. While the physiology of stumps of the upper extremity is of but minor importance, their pathology is fully as important as that of stumps of the lower extremity. Conical stumps, ulcerations, painful neuroses, etc., are just as common in stumps of the upper extremity and of the digits, and if these can be avoided by attention to details it is our duty to give the benefit of it to the patient.

Fig. 2.—Case of Wm. K., osteoplastic amputation of thumb.

Technic.—The evolution of this method is not only interesting, but also very important, as it demonstrates in successive phases the primary fail-

ures and difficulties, and only after overcoming these did it reach its present stage of, one might say, ultimate perfection. As the first attempts, which were based on a misconstrued conception, have been practically discarded, I do not intend to burden you with their detailed description; those who are interested in the subject will find them described in the earlier publications of Bier.[1] Instead I shall content myself by describing, in as few words as possible, the successive steps of the operation, as given by Bier in his latest monograph on the subject.[2]

As amputation of the leg, in view of its greatest requirement regarding functional ability, is the most important one, and possibly also the most frequent one, I shall confine myself solely to its description. Taking its technic for a prototype, all the other amputations being merely slight modifications, which can be readily adapted to the special limbs to be amputated.

1. A large anterior flap, with its corners rounded, is formed, its base occupying somewhat more than half of the circumference of the leg. While the flap is being prepared, an assistant draws it upward with sharp retractors; this manipulation renders tense the cellular tissue between the skin and the periosteum on the anterior surface of the tibia, which can then be readily divided by slight strokes of the scalpel. With a little care in this manipulation all injury to the skin or the underlying important periosteum can be easily avoided. Although this single large anterior flap is to be preferred, if the nature of the ailment for which the amputation is done permits it, a strict adherence to it is not necessary, and under no circumstance is it justifiable to sacrifice length of the stump to obtain it. One long posterior flap, or one short posterior flap and a somewhat longer anterior flap, will give practically as good results. In a word, any flap formation is applicable, but some care should be taken that the resulting cicatrix shall not lie directly over the stump.

2. The next step is the formation of the osteoplastic flap. To all intents and purposes, it is only in the insertion of this step wherein Bier's method of amputation differs from the other methods, hence considerable weight is to be attached to its execution. The osteoplastic flap is formed by circumcising the periosteum of the anterior surface of the tibia on three sides of a quadrilateral space, the lateral incisions encroaching slightly beyond the anterior and internal borders of the tibia. The edges of the periosteum are raised for a short distance from the bone and a thin plate of bone is sawn out of and parallel to the anterior surface of the tibia. On reaching the base of the periosteal incision, if the construction of the saw is such as to permit it, the teeth are turned anteriorly and the bone flap is sawn through, almost to the periosteum; if no such saw is at hand, a narrow but strong periosteal elevator is wedged into the slit and the flap elevated and broken at its base: if the broken edge is too rough, the jagged ends may be carefully chipped off with a rongeur. Finally, in order to give it more mobility, it is advisable to raise the periosteum for a slight distance upward from the tibia. I experienced considerable difficulty in my cases, as well as in an amputation by the Sabanjeff method, because I did not have a proper kind of saw; and, finally, had to resort to the Gigli saw. Bier has modified Helferich's bow saw, especially for osteoplastic amputations, but I have been unable to procure it at any of the New York surgical instrument dealers; this modification consists of an alteration in the two locks of the saw in such a manner that the saw can be fitted in, both in a vertical and a nearly horizontal position (the latter toward both sides); it is evident that a saw constructed on this principle would materially overcome some of the difficulties of this part of the operation. Although I was able to obtain a very satisfactory flap with the usual Gigli saw, I found it too unwieldy to enable me to do the more or less delicate work required. Recognizing these imperfections, I have constructed a new saw. It is not of a remarkable nature, as it is only an ordinary metal worker's or jeweler's saw frame, while its blade is a piece of a Gigli saw; although perfectly simple in its construction, I have no doubt it will be of considerable value in the sawing-out of the osteoplastic flap, as it enables the operator to use it in any direction that may be called for, and this without being compelled to change it. As yet I have had no occasion to try it, but I purpose to do so at my next amputation.[1]

3. The next step is the ablation of the leg, and the method of doing it depends upon the length of the anterior flap. Presuming it is sufficiently long to amply cover the stump, the ends of the incision are merely united by an incision on the posterior aspect of the leg. After division of the muscles of the calf and of the interosseous membrane, the osteoplastic flap being held upward, some care being taken not to injure it by rough handling, the tibia and fibula are sawn across at the level of the base of the osteoplastic flap. If the osteoplastic flap is sufficiently large to cover the ends of both bones, these are sawn across at the same height; if, however, it is long enough to cover the tibia only, it is best to divide the fibula at a slightly higher level, so as to practically exclude it from the stump formation; otherwise the fibular portion of the stump may become the seat of pathological disturbances.

4. Ligation of the bleeding vessels.

5. The osteoplastic flap is now turned over the divided surfaces of the bones, and its periosteal fringe is sutured to the periosteum of the tibia and fibula, or to fasciæ and tendons, in its proximity.

[1] *Archiv für klinische Chirurgie*, Band XLVI., p. 90; Archiv *für klinische Chirurgie*, Band L., p. 356.
[2] August Bier. Sammlung klinischer Vortrage, Teft 264

[1] Since writing this article I have had occasion to amputate another leg by this method, and tried to use this saw; very quickly, however, it was apparent to me that in its present state the instrument was altogether too crude in its construction, the objection being that the locks did not grip the saw with sufficient firmness to prevent it from slipping out. I am confident that with a slight modification in the mechanism this objection can be overcome very readily, and I am now at work in improving it.

6. Suturing of the skin.

While primary union is naturally the ideal mode of healing to be aimed at, it does not necessarily follow that its absence is bound to mar the ultimate result. If working in more or less infected areas, it is quite permissible to make use of the various methods of secondary suture without endangering the flap. I operated on my second patient in this manner, and yet the result is very good.

My experience with this method of amputation is limited to the two cases described in brief as follows:

Case I.—Alex T., sixteen years of age, a druggist's apprentice, was operated upon at Mount Sinai Hospital in 1898 for tuberculosis of the ankle-joint, and was discharged with a sinus on either side of the joint. Patient was readmitted to the hospital January 11, 1900, on which date examination revealed the following local condition: Above the internal malleolus a sinus one and three-quarter inches in depth leading into the joint; a similar sinus over the external malleolus; intense pain and tenderness over the entire joint, the lower third of the tibia and in the tendo-Achillis; considerable swelling and thickening of these structures. He was treated at first with iodoform-oil injections and immobilization. As there was no improvement I resected the tibio-tarsal joint on January 18th, removing apparently all of the diseased area. Subsequent to this operation, as well as prior to his admission to the hospital, the patient was also treated by venous hyperemia (Bier). On March 12th the joint was again examined and more tuberculous tissue removed. From time to time there appeared albumin in the urine, the liver became enlarged, and it was apparent that the patient was developing amyloid degeneration. To obviate this, I was compelled to abandon conservative treatment, and therefore on May 18th I amputated the leg by Bier's method. Patient was discharged June 10th with a slight sinus (caused by the drainage tube) which closed within a few days. The stump is now ideal in every respect; not only is there no pain, but not even the slightest tenderness; and the patient can press firmly against the stump and walk on it on the bare floor without causing him the slightest amount of pain.

The skiagraph of the stump (Fig. 1) taken eighteen days after amputation is very interesting; there is perfect union between the osteoplastic flap and the tibia, but there is no union between the fibula and the osteoplastic flap. Unquestionably it would be better if there were firm bony union here also, but its failure to unite is no drawback as far as function is concerned. Bier published a case in which there was no bony union of either bone, and yet the functional result was perfect.

The second case is unique perhaps inasmuch as, so far as I know, it is the first case of an osteoplastic amputation of the thumb.

Case II.—Wm. K., twenty-five years of age, a butler by occupation, injured with an icepick the dorsal aspect of the interphalangeal joint of the thumb; this was soon followed by suppuration of the joint, for the relief of which an incision was made on the dorsum of the joint; the process, however, continued to grow worse and he was admitted to the hospital August 14th. Immediately on admission, through-and-through drainage of the joint was established, but the joint surfaces and capsule were found to be entirely disorganized. These conditions alone called for amputation, which I performed August 25th by Bier's method. A proper saw was not at hand, hence in the course of the manipulation the osteoplastic flap was denuded of a considerable portion of its periosteum; in spite of this I sutured it to the sawn surface of the phalanx. Secondary sutures were inserted on account of the suppuration and tied three days later. Patient was discharged September 2d with a minute granulating surface. It was some time, however, before the wound closed definitely; a slight sinus persisted, at the bottom of which bare bone was felt for a considerable time, so that on many occasions I despaired of the ultimate result and feared that I would be compelled to remove the bone flap. I was agreeably disappointed when finally firm union took place, without the separation of a sequestrum. The stump, although quite thin in its terminal portion, is now perfect in every respect and leaves nothing to be desired.

The skiagraph (Fig. 2) taken six days after the operation shows distinctly the deep shadow of the osteoplastic flap.[1]

It is hardly proper to draw definite conclusions from the two cases reported, but in view of the undeniably poor functional results by the older methods, Bier's method appeals me to such a degree that I have deemed them worthy of publication. While I do not wish to be premature in my statements, it may be said with certainty that this method of amputation is the operation *par excellence* in all cases, with the exception perhaps of diabetic and senile gangrene.

350 West 58th Street.

PARASITES IN THE BLOOD.

By LEON T. LE WALD, M.D.,
of New York;
Instructor in Pathology in the University and Bellevue Medical College.

Of the true parasites which are found in the general systemic circulation, there are two of great importance. First the *filiaria sanguinis hominis*, causing the disease which we know under the term filariasis. For some time it was believed that this parasite could be found in the blood of an infected person only at night. But it has now been established that there are three varieties of the parasite—the one first described as occurring in the general circulation only at night and hence

[1] Thanks to the courtesy of Dr. A. G. Gerster, I had occasion ten days ago to amputate a leg by this method, for a rapidly growing sarcoma of the great toe. On account of the advanced age of the patient and consequent atheromatosis, there was considerable marginal necrosis of the flaps. I do not know as yet what the ultimate result of the case will be. Its consideration must, therefore, be postponed for the present.

known as the *filaria nocturna*; another found only during the day, *filaria diurna*, and another variety found at any time, day or night, *filaria perstans*.

An interesting anatomical peculiarity has just been observed by Dr. James Ewing of this city in the examination of the blood of a case of filariasis. The peculiar structure noted is a transverse striated appearance, giving much the appearance one sees in an earthworm. This was very beautifully illustrated in a photograph exhibited by Dr. Ewing and Dr. Buxton at the New York Pathological Society meeting October 10th, 1900. Another interesting point in regard to the filaria is the establishment of the transmission by means of the mosquito.

The second parasite we shall consider is the *plasmodium malariae*. Of this there has likewise been determined three varieties, producing, as you know, the three ordinary types of malaria; the tertian, the quartan and the estivo-autumnal, the latter also known as the irregular form and also as the tropical form. What we formerly called quotidian fever does not have the honor of a separate variety of organisms, but is due, we now know, to a double infection with tertian organisms, the two sets overlapping and maturing on alternate days. In the light of the mode of infection which we now know to be true of malaria—infection by mosquitoes—it is easy to understand how this double infection occurs.

As far back as 1850 Virchow saw the malarial parasite. Laveran and Golgi established the correspondence between its life cycle and the clinical cycle of the disease. That is to say, at the end of the apyretic stage of the cycle the parasite has arrived at maturity, and that in the shivering stage the parasite has reached the sporulating stage. During the succeeding hot and sweating stage the spores enter the red blood-cells and the fever comes to an end. This in tertian malaria takes forty-eight hours; in quartan, seventy-two hours. In the tropical form the time of the chill likewise corresponds with the sporulating stage of the estivo-autumnal parasite.

Now, this explains how the parasite maintains its existence in the human body, but does not show how it passes from person to person. Nor does it explain the presence of crescents and of flagellate bodies found in the blood. The presence of these latter bodies have been a puzzle for several years. The relation between these two bodies has been very close, crescents if watched having been seen to have given off flagellæ.

For years it has been suspected that mosquitoes had something to do with malaria, and, strange to relate, even savages in German East Africa, who lived in mountainous, and, therefore, non-malarial districts, noticed that when they went to the sea coast they acquired a fever. They said they were bitten by certain insects—mosquitoes—which they called *Mbu*. They gave the same name *"Mbu"* to the fever which they acquired, thus linking a cause and effect. Peasants in certain parts of Italy believe that the bite of the mosquito may be followed by malarial fever.

Drs. Manson and Ross, of England, working on this theory, were able to demonstrate in the stomach of mosquitoes which had bitten malarial patients flagellæ and spherical bodies. On watching these parasites in the mosquito's stomach, Ross found that they grew from six micromillimeters in diameter to 60 micromillimeters and that they retained the black pigment. And he also found after a large number of dissections from mosquitoes that this change took place only in one variety. Probably it is because the malarial parasite does not continue its development in the bodies of all kinds of mosquitoes that so much difficulty has been met with in establishing the truth of the theory.

It has been found that the parasite, after developing in the stomach of the mosquito, breaks up into small bodies which pass to the salivary glands and thus into the proboscis of the mosquito. The mosquito thus acts not only as the definite host of the malarial parasite, but also as the transmitting agent.

It is not necessary at this time to go into a discussion of the close relationship that people living in malarial districts have often observed between the prevalence of mosquitoes and the prevalence of malaria; that warmth and moisture and low moist places both conduce to malaria and to the breeding of mosquitoes; that protection of the body from mosquitoes by veils, wraps, screens and netting, also protects from malaria; that people going into malarial districts were always warned not to be out after sunset—the time when mosquitoes are particularly active; that the cultivation of the soil both prevents the breeding of mosquitoes in stagnant pools and the prevention of malaria; that wherever we find malaria we find mosquitoes. The converse does not hold true, but this is easily explained by the fact that so far it has only been ascertained that one variety of mosquito is capable of transmitting the disease. Hence we know why, for instance, northern regions are non-malarial, although explorers have found swarms of mosquitoes there.

The two celebrated yet simple experiments of Dr. Manson of London, which have now just been completed, leave no longer any ground for the most skeptical individual to stand upon.

Experiment No. 1 was as follows: From Rome he had mosquitoes which had bitten a patient suffering from tertian malarial fever, as demonstrated by a careful examination of the blood, sent to London where they were then allowed to bite a previously perfectly healthy individual—Dr. Manson's son. Here are the words of the patient: "I am twenty-three years of age. I was born in China, but have lived in this country since I was three years old and have never been abroad since, nor in any district in this country reputed to be malarial. I am healthy." Between August 29th and September 12th the young man was bitten many times by the mosquitoes thus obtained. On September 13th he began to feel languid and out of sorts and his temperature rose to 99° F. At mid-day he felt chilly and inclined to yawn.

At 4.30 p. m. he went to bed with severe headache, pain, in the back and bones, and a temperature of 101.4° F. On the following day temperature was 100° to 102° F. Patient had anorexia and an exaggeration of symptoms of the day before. September 15th he awoke feeling better, but at 2 p. m. felt chilly and at 4:30 his temperature was 103.6° F. At 9 p. m. diffuse sweating set in. September 16th temperature became normal. September 17th, temperature was 99° F. in the morning, but at 2 p. m. he had a chill and at 5 p. m. the temperature was 103° F. followed by sweating, and at 9 o'clock the temperature had fallen to 99.2° F.

Examination of the blood showed many tertian parasites. The edge of the spleen could be felt on deep inspiration, and there was a slight feeling of discomfort in this region. He was then given ten grains of quinine and the following day ten grains more and five grains every eight hours. No more parasites were found after 5 p. m. of this day. September 19th, temperature normal and appetite had returned. September 25th in good health, no recurrence of malarial symptoms.

Experiment No. 2 was as follows: A wooden hut constructed in England was shipped to the heart of the malarial district of Italy, where the permanent inhabitants all suffer from malarial cachexia and where the laborers who come from healthy parts of Italy for harvesting purposes all contract fever. The only precaution taken by the experimenters who lived in the wooden hut was to have the windows and doors most carefully screened and their beds protected by mosquito netting. During the day they went about as others, but were always careful to be indoors from sunset to sunrise. From early in July until September 21st, they have enjoyed perfect health, while their neighbors in marked contrast were all either ill with fever or had suffered with severe malarial attacks.

You will be interested now in knowing the distinguishing characteristics of the mosquito which carries the infection. It is of the variety known as *Anopheles* and differs from the more common variety of mosquito known as *Culex*, by the following peculiarity. Its palpi are about as long as its proboscis, while in the *Culex* the palpi are very short. In the resting stage the *Anopheles* projects at right angles from the surface while the *Culex* holds its body parallel to the surface. Another distinguishing point is that the *Anopheles* holds its beak and body in one line while the *Culex* holds its beak and body at angles with each other, thus giving a humpbacked appearance. The larva can be distinguished in the pools of water by the fact that the body of the *Anopheles* larva is parallel with the surface of the water, while that of the *Culex* hangs with the head downward.

Too much credit cannot be given to the work of Dr. Manson in proving his theory, and it only remains to destroy as far as possible the breeding of the *Anopheles* mosquito to render malarial districts habitable.

GENERAL REMARKS ON THE COMBINATION OF ETHER (57 PARTS) AND CHLOROFORM (43 PARTS), KNOWN AS THE M. S. MIXTURE.

By EDWARD ADAMS, M.D.,
OF NEW YORK;
MEMBER OF THE GERMAN HOSPITAL HOUSE STAFF.

This article is based upon three hundred narcoses induced by the author and deals chiefly with the practical personal observations made by him. Little claim to originality is made, for most of these observations have been made before, and it is intended to relate the experience of a hospital interne as briefly as possible.

The following subdivision of the subject seems most practical: (1) Preparation of the narcotizer. (2) Preparation of the patient for anesthesia in narcotizing-room. (3) Choice of anesthetic. (4) Stages of anesthesia. (5) Conditions influencing anesthesia, such as (*a*) heart-action, (*b*) respiration, (*c*) vomiting, (*d*) position of patient, (*e*) accidents during anesthesia (*f*) concluding remarks, under which head the after-treatment should be considered and also the emergencies occurring at this time and their methods of treatment.

1. *Preparation of the Narcotizer.*—In operations about the head, face or neck it is well to allow an assistant to give the anesthetic until the operative field is thoroughly scrubbed and prepared for the surgeon. In the meantime the anesthetist should disinfect his hands thoroughly and put on a sterilized gown. A sterilized mask should be prepared and the bottle containing the anesthetic covered with a sterilized towel. Plenty of towels, a mouth-gag in good working order, a pair of tongue forceps, a soft sponge on a long, steel sponge-holder, several hypodermic syringes and solutions of camphor, strychnine, digitalis, spartein, atropine, whiskey, nitroglycerin and amyl nitrite should be in readiness.

2. *Preparation of the Patient.*—It is understood that the patient has been properly prepared for anesthesia. Before beginning to administer the anesthetic, false teeth (if the patient wears them) should be removed. Do not leave this to the orderly or nurse; see to it yourself. Examine carefully the patient's heart, as well as the lungs, and look at the eyes to see if there is an artificial one present. If so, have it removed. Previously the urine should have been examined for albumin and casts. All bandages should be loosened. Apply vaseline on the cheeks, chin and nose, and you are then ready to begin the anesthesia. See that the room is quiet, do no more talking than is absolutely necessary, tell the patient that you are going to administer the anesthetic very slowly and then pour a few drops on the mask, at first holding it at some distance away from the face and gradually bringing it closer and closer. Talk to the patient in a low, impressive tone and try, if possible, to gain his confidence, for this will greatly help you in your work.

3. *Choice of Anesthetic.*—As a rule, chloroform is chiefly to be preferred (*a*) in renal disease, (*b*) in pulmonary disease, (*c*) in obstetrical cases, (*d*)

in children, (*c*) in old patients, (*f*) in alcoholics, and (*g*) in operations about the head. Ether is usually given by preference when extreme prostration exists and in cardiac cases. Personally I know of no contra-indication to the use of M.S., for there have been patients here to whom neither ether nor chloroform alone could be administered, but in whom this combination gave admirable results.

4. *Stages of Anesthesia.*—The stages of stimulation and excitement quickly merge into one another, sensibility being slowly impaired and reflex action continuing. At about this time some of the patients become violent, this being especially marked in alcoholic and very robust patients. To patients giving an alcoholic history I have made it a practice to give 8 minims of Magendie solution at least half an hour before anesthesia, and it is really surprising how quietly they take the anesthetic. At the stage of excitement some patients begin to vomit, and when this is the case it is best not to crowd the anesthetic. Allow them to vomit; in so doing they will partly come out, but afterward they seem to go under more quickly. At this stage the muscles are quite rigid, the face is livid and the pulse and respiration are increased in both frequency and force. As soon as the excitement and struggling have passed the patient goes into the stage of anesthesia in which nearly all the reflexes are abolished except those of the involuntary muscles. As a sign of relaxation I generally rely upon the muscles of the arm in flexion in order to see if any stiffness is present. It has also been my experience that a patient is not thoroughly anesthetized until the muscles of the jaw are completely relaxed. If at this point the anesthetic is still further administered, the patient will go into collapse, this being evidenced by the cyanosis of the finger-nails and later by that of the mucous membranes; respiration will become slow and shallow, the pulse feeble and slow, at times stopping suddenly without warning; the pupils become dilated and do not react to light, and unless prompt measures for resuscitation are taken death ensues.

No one sign can be relied upon as to how deeply the patient is under the anesthetic; the reflexes in connection with the pulse and respiration must be considered together, for I have seen cases in which the patients have been deeply under the influence of the anesthetic and in which the eye reflexes were present and others in which the patients were hardly under although no reflexes were present. If morphine is given before the operation it will cause a contraction of the pupil. If the pupils are dilated do not think that the patient is deeply under, for sometimes the pupils suddenly become dilated when vomiting is about to set in. If you are in doubt as to the condition present the pulse and respiration will act as guides. If the patient is deeply under the pulse will be slow and regular, as a rule, and the respiration somewhat slow and shallow. If the mask is now removed for a few minutes, it will be noticed that the pupils will contract at once, the pulse become stronger, and respiration stimulated. If, however, the pupils are dilated because the patient is not under control, and if in connection with the dilated pupils there is a corresponding increase in rapidity of both pulse and respiration, with spasmodic contraction of the diaphragm and attempts at deglutition, all of which signs predict vomiting, the anesthetic should be crowded. If, however, vomiting is inevitable, the mask should at once be removed, the patient's head turned to one side, and the mouth wiped with a towel. At times it will be necessary to let the patient come entirely out. Of course, such an occurrence is very annoying to the operator, as he cannot proceed until the patient is again under the influence of the anesthetic.

In regard to heart-action and pulse, as a rule, I place a finger on the radial artery before the anesthetic is administered in order to determine the rate, quality and characteristics of the pulse. At this stage the pulse is generally quite rapid, forcible and slightly irregular, as the result of excitement or nervousness. This is the case until the stage of anesthesia is reached, at which time the pulse becomes slower and more steady. If the anesthetic is administered beyond this stage signs of cardiac failure will be evidenced by a weak, rapid, fluttering, irregular pulse. If the patient shows signs of cyanosis, remove the mask for a moment or two. The color will at once reappear and there will be a marked improvement in the character of the pulse. The following conditions will cause an increased pulse-rate: (*a*) When the patient is about to vomit; (*b*) during dilatation of the sphincter ani muscle; (*c*) in operations about the stomach or intestines; (*d*) after the loss of a large amount of blood; (*e*) when the patient is recovering from the operation. A decreased pulse-rate is noted under the following conditions: (*a*) In operations about the face or neck; (*b*) removal of a large abdominal tumor, as shown by the evacuation of the contents of an ovarian cyst or removal of a large fibroid tumor; (*c*) in hernia operations from pressure on the spermatic cord or testicle; (*d*) when the patient is about to go into collapse.

Always place your finger on one of the arteries during the operation in order to watch the pulse. It is a matter of personal preference which vessel is selected. Usually the facial, temporal, carotid or radial is chosen. Personally, I prefer the first-mentioned, although there are times when the pulse cannot be well felt at the facial, but it is very good at either one of the other arteries. From time to time the pulse should be noted at one or other of the vessels, in addition to the one you constantly have under observation. As a rule, the pulse averages about 70 during the operation, but any of the conditions named heretofore may cause it to be as rapid as 150 or as slow as 40 per minute.

As to respiration, when the anesthetic is first administered this may be quite rapid, as most patients are afraid to breathe naturally, thinking that they will go under more rapidly if they do not

do so. According to my observation, this is a mistake. I usually ask the patients to breathe in normal manner. When they are half under the influence of the anesthetic the respirations are short and rapid, and the nearer the approach to the stage of anesthesia the more steady and slow they become. If now the narcosis is still further pushed, the respirations become slower and more shallow and finally cease. Always try if possible to keep the patient's head to one side and keep the lower jaw well forward, this being easily accomplished by placing two fingers beneath the angle of the jaw and throwing it forward. This will prevent the tongue from dropping backward and thus obstructing the air-passage. If the patient does not breathe well, place the mouth-gag in position and draw the tongue forward with the forceps. If there seems to be either mucus or vomitus obstructing the air-passage, use the sponge on the sponge-holder and try to keep the pharynx clear of any foreign bodies. Increased respiratory movements usually show that the patient is coming out, but, then, the respirations may be stimulated reflexly from some manipulation of the peritoneum, intestines, or stomach. When the respirations become slow and shallow, remove the mask and if the patient is not under too deeply the respirations will be at once stimulated. On the other hand artificial respiration may have to be resorted to and Sylvester's method is the one to be preferred. Stertorous breathing can be overcome by removing the mask for a moment or two, but sometimes in very stout people with short necks, and in operations about the face or neck in this class of patients, the snoring and disagreeable respiration will persist throughout the entire anesthesia, no matter what means may be taken to overcome the same. Certain positions also seem to influence the respirations, the most common being the Trendelenburg and nephrotomy positions.

The accidents which may occur during anesthesia are asphyxia and cardiac failure. The former has already been dealt with, but I may add that sometimes a few drops of amyl nitrite will have a stimulating effect. Possibly tracheotomy may have to be resorted to, but this is not often necessary. Cardiac failure usually occurs as a result of too deep an anesthesia. The premonitory symptoms are extreme pallor, sudden wide dilation of the pupils, cessation of respiration, pulse at first very rapid, finally becoming imperceptible. The anesthesia should at once be stopped, the foot of the table raised, and artificial respiration should be performed at once. Hypodermic injections should be freely given and for a rapid stimulant of the pulse I do not believe there is anything better than 20 minims of a 25-per-cent. solution of camphor ether, as this acts almost instantly. At least two or three of these injections should be given, as well as 10 minims of a 1-per-cent. solution of strychnine, nytroglycerin, digitalis, whiskey, caffeine, camphor and spartein can also be used. If necessary an intravenous infusion of salt solution may be given. This is used at a temperature of about 120° F.; from 800 to 1500 c.c. may be given. I do not believe hot rectal injections are of much value for rapid stimulation, but shall dwell upon this subject later.

As soon as the operation is over, the patient should be placed in bed. This should be previously warmed and, if not, hot-water bags should be placed about the legs and thighs. At this time a hot rectal injection is very beneficial. This usually consists of 8 ounces of salt solution and 2 ounces of whiskey, the former given to quench the thirst, the latter for the stimulating effect. If necessary this should be repeated in six hours. If the patient is suffering from shock he should be treated in the manner described heretofore. Magendie solution, in small doses, may be given to relieve pain. In order to prevent asperation the head should be turned to one side and the jaw kept well forward. The time for the restoration of consciousness varies, the average being about twenty minutes; during this time the patient should not be left alone.

Do not under any circumstances crowd the anesthetic because you are told to get the patient under immediately; take your time, even if it annoys the operator. It usually requires from six to twelve minutes to get a patient under. Alcoholics require a longer time—in fact, I have seen some who could hardly be kept under the influence of anesthetic at all. Of course, such a narcosis will be very disagreeable to the surgeon, but always remember the fact that the welfare of the patient is in your hands. Always be on the lookout for danger-signs and do not be afraid to inform the operator if anything goes wrong. Speak right out in a clear, forcible tone and state to him the exact condition present.

Do not place too much dependence on any one sign. Take in the general condition, the nature of the operation, its duration, and how the patient is bearing it. Above all, do not lose your head. Keep cool and work quietly and rapidly. If any accident should occur inform the surgeon at once. Be careful in anesthetizing infants and very old people, for cardiac failure comes rapidly, with little or no premonition.

Brief Summary.—The chief advantages of M. S. are the following:

1. Stage of excitement and struggling are not marked.
2. It requires a short time to get a patient under, five or ten minutes.
3. Very little of the anesthetic is required. On an average about 40 c.c. are used an hour.
4. It is a comparatively safe anesthetic.
5. It is very pleasant to take.
6. The after-effects are not marked.
7. Patients recover quickly.
8. It can be used in nearly every condition in which either chloroform or ether is employed.

Sale of Horse-Meat Forbidden.—The Board of Health met this week and by a unanimous vote prohibited the future slaughter of horses in this city and the sale of meat from all such animals.

A REPORT OF SOME CASES OF ABDOMINAL SURGERY, WITH REMARKS ON THE DIAGNOSIS OF CARCINOMA OF THE CECUM AND THE SURGICAL TREATMENT OF CARCINOMA OF THE LIVER AND THE GALL-BLADDER.[1]

By CHARLES GREENE CUMSTON, M.D.,
of Boston, Mass.

These remarks might be more properly entitled a "potpourri" of surgical subjects and the only excuse that I have for offering them to this Society is that at the present time we are far from knowing all that there is to know about a number of affections of the various abdominal viscera and how far they may be dealt with surgically. The lesions of the abdominal viscera are in many instances an unknown quantity until the abdomen has been opened, and oftentimes the diagnosis made before laparotomy is done is most uncertain. The various manifestations of tertiary syphilis affecting the abdominal viscera are as yet very imperfectly known, and I believe much remains for surgery to find and to deal with in the abdominal manifestations of this universal and protean affection.

Case I.—Mr. B. S., aged forty-one years; married; the father of four children, two of whom died at birth, while the two living ones, who are the last of the series, are healthy to all appearances. The personal and hereditary antecedents of the patient are without interest. He denied having had syphilis, and he gave no evidences of overindulgence in alcohol. About three months before I saw the patient, he had become suddenly jaundiced, and after a short time pain was complained of in the right hypochondriac region, as well as in the right shoulder-blade. By palpation the border of the liver could be made out extending about four fingerbreadths below the ribs, and reaching over toward the median line. There was a slight amount of ascites, and the patient had lost ten or twelve pounds in weight since the commencement of his illness. There was no edema of the lower extremities and at no time had there been melena or hematemesis.

A careful examination of the other abdominal viscera, as well as of the heart and lungs, failed to reveal any other abnormal condition present. A careful search for enlarged lymphatic glands in the axilla, groin, supraclavicular region, or in the neck, proved negative. The diagnosis of malignant disease of the liver or gall-bladder was made, and an exploratory incision was advised and accepted.

An incision was carried along the outer border of the rectus muscle over the growth, and the enlarged liver was exposed after breaking down numerous friable adhesions that it had contracted with the parietal peritoneum. The liver was very hard to the feel, and two nodules about the size of English walnuts projected from the anterior surface of the right lobe near its border; their contour was regular, and their surface somewhat nodular; in color they were lightish yellow. There was no evidence of carcinoma of the liver, gall-bladder or peritoneum. An incision was carried across both nodules, and a large amount of cheesy matter removed, leaving two rather clean-cut, cup-like cavities in the liver. These cavities were packed with gauze and the abdominal wound was closed excepting at the upper part which gave exit to the drains. These were removed at the end of four days and the abdominal wound remaining closed rapidly by granulation.

The patient was placed on iodide of potassium, four grams a day; as his stomach withstood the iodide perfectly, he was kept on it for three months and a half. The jaundice completely disappeared after about five weeks of treatment with the iodide, and at the end of three months the liver had decreased in size so that it could no longer be made out by palpation or percussion beyond its natural limits. The patient has been under observation ever since, now a period of eighteen months, and has remained perfectly well. This is clearly a case of gummata of the liver, but I have never been able to make the patient admit that he had suffered from syphilis.

Case II.—Miss X., aged nineteen years; referred by Dr. Charles W. Knowlton of this city. A year previous to our seeing the patient, she had suffered from a typical attack of gall-stone colic, with all the characteristic symptoms of yellow skin and conjunctiva, clay-colored stools, anorexia and severe pain in the region of the gall-bladder. She made a good recovery after a few weeks of treatment, and, although the calculi was searched for in the stools, none had ever been found.

We saw the patient during a second attack of jaundice and pain in the region of the gall-bladder in May, 1897. At this time the skin and conjunctiva were deeply jaundiced. Anorexia was almost complete, the stools were white, and the tongue thickly coated. Pulse 60 per minute; temperature 36.5° C. (97.7° F.). The patient was a very slightly-built girl, and by palpation of the abdomen the presence of a large globular tumor in the right hypochondriac region, which might be about the size of a large grape fruit, was made out. This tumor was extremely sensitive to pressure. A diagnosis of a gall-bladder filled with calculi was made, and this diagnosis was concurred in by Dr. David W. Cheever and Dr. Edgar Garceau who saw the patient.

After a preparatory course of medical treatment extending over two weeks, the patient was operated upon. An incision parallel with the outer border of the rectus was made, and when the peritoneum was reached, what appeared to be the fundus of the gall-bladder was distinctly felt adherent to the serous membrane. The latter was picked up and carefully incised to the extent of about four centimeters, and when this opening had been made it was found that the supposed gall-bladder was adherent to the peritoneum over quite an extensive area. The organ was carefully separated from the peritoneum by breaking down

[1] An address delivered before the Cheshire County Medical Society, Keene, N. H., Oct. 9, 1900.

the adhesions all around the edges of the incision, but as the organ was nicely walled from the peritoneal cavity it was found unnecessary to pack the incision with gauze. The aspirating-needle was slowly introduced for about three or four centimeters, but did not come into contact with any calculi, and a vigorous use of the aspirator did not withdraw a single drop of fluid. Several attempts were made, but no gall-stones were encountered by the needle, and nothing but a little dark blood would come away when the latter was withdrawn.

Not being able to account for the condition of affairs present, the adhesions between the organ and the peritoneum were broken down, and, when the hand could be introduced into the free abdominal cavity, our surprise was great when we found that there was a large mass the size of a fetal head extending from the under surface of the liver and dipping down well into the pelvic cavity. The surface of this mass was very nodular and hard. Raising up the borders of the incision with a broad retractor, the cavity was inspected and a small gall-bladder was seen in its normal position. The supposed gall-bladder was a large carcinomatous liver, and, as a radical operation was out of the question, the abdominal wound was immediately closed. The patient died shortly after the operation, but unfortunately no autopsy could be obtained.

Case III.—Mr. S., aged thirty years; married; seen in consultation with Drs. George W. Clement and L. H. Guptil, when the following history was obtained. The patient had always been well up to the time that he contracted typhoid fever about six weeks before we saw him, and for which he had been attended by Dr. Guptil. The fever had run its usual course, but when convalescence was about to take place the temperature, which had been gradually reaching the normal, went up after the patient had complained of a sudden pain in the right iliac fossa which had occurred after an enema had been administered to unload the large intestine. This sharp sudden pain was not of long duration, and at the time of its occurrence neither pulse nor temperature seemed to be affected, and there were no signs of intestinal perforation nor of collapse.

A few days after this attack of pain the temperature began to go up, and the patient complained of some pain in the right iliac fossa. Dr. Clement, who then saw the patient, found a mass in the iliac region which he diagnosticated as an abscess, probably starting from the appendix. The patient was etherized and an incision over the most prominent part of the tumor was made, and when the peritoneum was reached a large amount of pus was evacuated. The cavity was explored and seemed to be well limited, so that no attempt to find the appendix was made. Drainage-tubes were inserted and after about two weeks' time all discharge had stopped and the wound had closed nicely.

About three weeks after the operation for the iliac abscess, the patient, who had been doing nicely, began to complain of pain in the region of the gall-bladder and in the right lumbar region, and, as the temperature was going up, my opinion was asked for. Examination showed a tall, blond man, with a very hectic appearance. There had been on several occasions a slight hemorrhage from the gums. The tongue was covered with a white fur and the skin and conjunctiva were very slightly jaundiced. The patient presented all the aspects of one suffering from a low form of sepsis. The temperature was 38° C. (100.4° F.) and there was a weak wiry pulse of 110 to the minute.

Abdominal palpation showed a large mass in the region of the liver and which could be better felt by placing one hand in the lumbar region and the other over the anterior abdominal wall. This mass appeared to give rise to a slight sense of fluctuation and appeared to be rather globular in shape. On pressure the patient complained of much pain in the region of this tumor. In my opinion one of three conditions was present, which I named in order of probability, *viz.*, an abscess of the liver, empyema of the gall-bladder, or pyelonephrosis. Exploratory incision was advised in order to evacuate the pus and, believing that it was the liver that was most likely involved, a buttonhole was made over the most prominent part of the growth in the anterior abdominal wall. When the peritoneum was reached it was found that the tumor had contracted intimate adhesions with the serous membrane, and after these had been broken down sufficiently to allow the finger to be introduced, it was found that the liver was adherent everywhere.

The adhesions were broken down and the abdominal cavity was explored. The tumor was the greatly enlarged right lobe of the liver, the gall-bladder could not be found, while the right kidney, which was normal in size, had been pushed down into the pelvis by pressure from the enlarged liver. The external aspect of the liver was perfectly normal as to color; by carefully palpating it no distinct point of fluctuation could be made out, but while doing this a few drams of thick pus escaped, but we were unable to trace its origin. An aspirating-needle was inserted into the most prominent part of the liver in several directions, but no abscess cavity could be located. After careful exploration for pus, none being found further than the small pocket which was evacuated and of which we have already spoken, the cavity was packed with gauze and part of the abdominal incision closed.

The patient survived forty-eight hours. At the autopsy the following condition of affairs was discovered: In the right iliac fossa a large abscess cavity was found at a point where some of the small intestine was adherent to the parietal peritoneum. This abscess cavity, which contained about 150 c.c. of greenish-yellow pus, did not seem to have any connection with the abscess which had been opened three weeks previously by Dr. Clement. The right kidney contained several infarcts. The liver was enlarged considerably and had contracted adhesions with the stomach, large

intestine and parietal peritoneum. It was light brown and greasy. The right lobe of the liver, which had been explored with the aspirating-needle during the operation, was found to contain a well-formed abscess about the size of a lemon near its free border, but which was distinctly in the midst of the parenchyma of the organ, as much as two centimeters of liver tissue surrounding it on all sides, and no indication of its presence either by the color or tumor on the surface of the liver could be found. It is very probable that this abscess was in a miliary state at the time of the operation and it developed rapidly, because, were it otherwise, pus would have been withdrawn from it when the needle was introduced. No other trace of abscess formation could be found in the liver although carefully searched for. This case is particularly interesting in point of view of diagnosis and is a pathological rarity, inasmuch as pyemia following typhoid fever is of rather rare occurrence, particularly the location of pus in the liver.

Case II.—Mr. B., aged twenty-eight years; single; was referred to me by Dr. Ernest Burden of Brookline with the following history. In the early part of November, 1899, the patient began to complain of a general weakness, and at the same time an alternating constipation and diarrhea supervened. After a week or so, he was obliged to keep his room, the diarrhea and constipation becoming very troublesome. Anorexia was marked, the tongue thickly furred, and the temperature ranging between 38.5° C. (101.3° F.) and 39° C. (102.2° F.). The patient gradually lost flesh during this illness until he had lost forty-seven pounds. Things continued pretty much the same until within a week before I saw him, at which time his physician noticed a large tumor on the left side of the abdomen and to which his attention was called by the patient who experienced a sensation of fulness in the abdomen and what he described as prickly pains.

In September, 1899, I had operated on this man for a large congenital inguino-scrotal hernia, doing a Bassini's operation. The hernia was composed entirely of omentum, and at the time of the operation about a pound and a half was ligated and removed. The patient made an uninterrupted convalescence and a very satisfactory result was obtained. At the time of operating for the hernia he was a very healthy man and presented no other pathologic condition.

The patient first felt the fulness one morning; as he arose from his bed he felt a weight at the site of the operation and placing his hand there found that a small bunch was protruding through the inguinal canal.

I saw the patient the latter part of December, 1899, about eight weeks after the commencement of his present illness. He was pale, the complexion rather sallow, the tongue thickly coated, and a temperature of 38° C. (100.4° F.). The pulse was regular, full and 78 to the minute. Examination of the abdomen revealed a globular mass completely filling up the left half of the abdomen; its surface was very slightly lobulated and was somewhat tender on pressure. There was complete dulness on percussion from the costal border down into the iliac fossa on the left side. No enlarged lymphatic glands could be discovered at any of the usual regions. The urine was dark colored and had a specific gravity of 1021.

My diagnosis was a probable sarcoma of the left kidney, but, being somewhat in doubt as to my diagnosis, Dr. A. M. Sumner kindly saw the patient in consultation, and he rather inclined to a diagnosis of primary tuberculosis of the spleen. We, however, agreed that an exploratory incision was justifiable, and the patient was admitted to the hospital.

A small buttonhole incision was made over the most prominent part of the tumor, and when the peritoneum was reached it was found intimately adherent with the mass. A small piece of the growth was excised and submitted to a pathological examination. The report of the pathologist returned to us was that it was a typical specimen of myxosarcoma, but of what organ it was impossible to say.

On the strength of the pathological diagnosis I concluded that my diagnosis of renal sarcoma was correct, and I accordingly advised the removal of the kidney which was accepted by the patient. Two days later a long incision, measuring about 35 centimeters, was made over the tumor. We broke down the adhesions and while working toward the median line, the hand suddenly entered the general peritoneal cavity. Words can hardly convey to the mind the condition of affairs that was present. The intestines, both large and small, were all matted together in a dense, cheesy tissue, which was rather friable and when handled gave rise to a considerable venous hemorrhage which it was rather difficult to control. A careful exploration decided very quickly that nothing could be done for the patient's relief and the abdominal wound was closed.

To make a long story short I would say that the patient progressed nicely after the operation and that the wound closed perfectly. His appetite improved and his bowels became more regular. Believing that I was dealing with a diffuse syphiloma of the intestines, I decided to place the patient on iodide of potassium in large doses, and this was begun nine days after the operation. When the dose reached four grams of iodide daily, the patient rapidly improved, so that at the end of two months no trace of tumor could be detected within the abdomen. He slept well, ate ravenously, and six months after the operation weighed 159 pounds, which was a gain of 49 pounds.

In closing the history of this interesting case, I would say that in speaking with the pathologist who examined the specimen he told me that the possibility of tuberculosis was out of the question, and that, although this specimen examined microscopically represented a perfect type of myxosarcoma, there was no doubt in his mind but that he was in error and that the lesion was syphilitic.

Case V.—A young man, aged twenty-one years, who was active in athletics at his college, was taken sick as follows. The afternoon before he had taken unusual active exercise in the gymnasium, ate a hearty meal, and retired early feeling perfectly well. Upon awaking the next morning he complained of a severe pain in the right iliac fossa which confined him to his bed and increased in severity as the day went on. His family physician, of homeopathic persuasion, saw him late in the afternoon and found a pulse of 110 and a temperature of 39° C. (102.2° F.). The usual treatment for acute appendicitis was apparently given here, namely, ice-bags to the iliac fossa and immobilization of the bowels by opium. The next morning the condition of affairs was practically the same, but the patient, who had had a severe chill at about five o'clock in the morning, complained of considerable pain in the left side of the abdomen.

By night the boy's condition had become considerably worse. He was vomiting a bile-colored liquid and the body was covered with a cold perspiration. Being alarmed by his condition, the family desired a surgeon, but as the request was laughed at by their physician, the latter was discharged from the case and I was summoned.

Fig. 1.

Diagrammatic figure illustrating case of gangrenous appendicitis, with metastatic abscesses on left side of abdominal cavity.

On examination I found a well-built young man presenting all the classical symptoms of an acute septic process within the abdomen. Examination showed a large tumor in the right iliac fossa and another one about the size of a fetal head in the left side of the abdomen midway between the crest of the ilium and the border of the false ribs. Diagnosis of perforating appendicitis with secondary abscess formation within the abdomen on the left side was made and operation was advised and performed an hour later. We opened the right iliac fossa by an incision carried over the most prominent part of the tumor and parallel with Poupart's ligament. A large amount of pus and fluid feces escaped, and the abscess cavity was thoroughly washed out with peroxide of hydrogen. We next turned our attention to the mass on the left hand side of the abdomen over which, in its most prominent part, we made an incision parallel with the border of the rectus muscle to the extent of about ten centimeters. When the peritoneum was reached we found the omentum closely adherent to it, and breaking through this we entered an abscess cavity situated between two intestinal coils.

By carefully exploring the parts with the finger a number of adhesions were broken down, each one walling off a small abscess pocket; some ten or twelve abscess cavities were evacuated, care however being taken not to break into the general peritoneal cavity. Three large drainage-tubes were then introduced in different directions. The cavity in the right iliac fossa was also drained. When inserting the tubes the appendix was seen at the bottom of the wound pointing directly downward toward the bladder and adherent to the surrounding bowel; it was peeled out from its bed and removed without any very great difficulty. The patient made an uninterrupted, though slow, recovery, and at the present time, thirteen months after the operation, is in excellent health.

I interpret this case as being an acute gangrenous appendicitis due to torsion of the appendix during violent physical exercise. I have met a number of cases of appendicitis occurring in young athletic men in robust health, and almost all of them were of the fulminating variety, so that now I always advise immediate operation regardless of the symptoms present in this particular class of cases of appendicitis, and I have never yet had cause to regret it, as in every instance the appendix was sloughing and ready to break down even as early as twelve hours after the commencement of the pain. This, however, is the only example of secondary abscess formation within the abdomen due to an acute suppurating appendicitis with which I have met, with the exception of the liver.

(*To be Continued.*)

MEDICAL PROGRESS.

Management of the Breast During Lactation. The lack of cleanliness in caring for the nipple is responsible for nearly all cases of infection and abscess of the breast. C. S. Bacon (*N. Y. Med. Jour.*, Jan. 12, 1901) advises that the nipples be washed with clean water before nursing and with 75-per-cent. alcohol after nursing. They should always be protected by clean dressings, and handled with sufficient care to avoid any abrasions. When wounds occur shields are of great value, but they should be large enough to cover the areola and cause no pinching of the nipple. Alcohol seems to be the best antiseptic

to apply to the abrasions. When the first symptoms of infection have appeared, nursing from that breast should cease and the breast should be supported and put at rest by a proper bandage. A circular bandage may be sufficient if the breasts are held upward and inward toward the median line. The application of an ice-bag is an important adjuvant to the treatment of an infected breast. If pus is suspected a hypodermic needle may be used to determine its presence and it should be evacuated as soon as it is discovered under a local or general anesthetic.

Coxa Vera.—This condition consists of a deformity of the upper epiphyseal region of the femur, owing to which the head of that bone sinks to a lower level than normal, even in extreme cases almost touching the lesser trochanter. During the last twelve months W. E. Bennett (*Birmingham Medical Review*, Dec., 1900) has had four cases of this disease come under his observation, and he reports them in detail. The writer gives a history of the literature on the subject, which shows that of ninety cases reported by various observers, sixty-eight were of the male sex. Bennett classifies coxa vera, according to the age of the patient, as follows: (1) Congenital; (2) childhood; (3) adolescence; (4) adults—osteomalacia. He considers only the coxa vera of adolescence which has been subdivided, according to the signs and symptoms, by Hofmeister into three groups, thus: (*a*) Characterized anatomically by downward displacement of the head of the femur and elevation of the great trochanter above Nélaton's line, the only signs being shortening of the limb and prominence of the great trochanter and the only symptoms more or less pain at the hip-joint and limited power of abduction, together with a slightly limping gait. (*b*) Has all the characteristics of group 1, plus a diminution of internal rotation, due to the curving backward of the head of the bone, the limb being generally slightly everted. (3) Has all the characteristics of group 1, plus diminished external rotation, due to the head of the bone being curved forward, the foot and limb being generally inverted. The writer discusses the etiology, age of onset, the signs and symptoms, the diagnosis and prognosis of the disease, and says that in treatment there are the three following indications: (*a*) The general condition upon which depends the softening of the bone; (*b*) the pain, and (*c*) the deformity. Rest quickly does away with the pain, and also checks the advance of the deformity, the body weight being removed. When the deformity is very marked, subtrochanteric osteotomy of the femur or cuneiform osteotomy of the neck of the bone may be done. In very few cases, however, does the writer think that operative procedure will be necessary, because of the extent of the relief his patients obtained from rest in bed. Bennett believes that a diagnosis is absolutely impossible without the use of the Roentgen rays.

A New Method of Herniotomy.—A. L. Dentu (*Revue de Chir.*, Dec. 10, 1900) states that for the last twelve years he has performed the method of operating for the radical cure of inguinal hernia detailed as follows: The aponeurosis of the external oblique muscle is exposed through the same incision as in the Bassini operation and then cleaned up very carefully. The sac is sought among the tissues of the cord distal to the external ring and dissected out by any procedure of choice. Then, within the inguinal canal, without slitting up its anterior wall, by traction and dissection the balance of the body and the neck of the sac are freed into the internal abdominal ring. Just lateral to the site of this ring a small incision, about a centimeter long, is made through the external oblique aponeurosis in the direction of its fibers. Through this hole a special forceps is passed bluntly tearing its way into the upper extremity and along the course of the inguinal canal as far as the external ring. Here it sizes the fundus of the sac and draws it upon itself upward and outward through the little hole. At this point the neck may be twisted and doubly ligated or transfixed and ligated, the fundus cut away and the stump returned to the internal ring or included in the mattress sutures which close the little incision. The redundancy of the anterior wall of the canal is corrected by making a fold in it parallel to its long axis and secured by mattress sutures placed vertically to the surface of the abdomen at intervals of about one centimeter. The edges of the external ring are finally brought together by a similar plan. Thus the canal and the ring are narrowed so as to allow the cord to pass freely through. This method is found to be very applicable to cases in which the sac can be entirely emptied primarily or after freeing slight adhesions. Its advantages are that the external oblique aponeurosis is nowhere divided over the canal, that the apposed surfaces are not cut edges, but broad intact areas, and that all the sac is obliterated as in the Bassini method. His results are as good as with the Bassini operation.

Pregnancy After Removal of Both Ovaries.—Cases of pregnancy following removal of both ovaries and tubes are rather rare. M. A. Morris (*Boston Med. and Surg. Jour.*, Jan. 24, 1901), reports the occurrence of such a case in his practice. The patient had had dysmenorrhea for a number of years, in fact, since the birth of her boy who was four years of age at the time she consulted the writer. After examination and some preliminary treatment she was operated upon for disease of the ovaries. The right ovary contained a cyst as large as a hen's egg and the left ovary a hematoma nearly as large as the cyst. The ovaries and tubes were tied off with silk quite close to the uterus and removed; the patient made a rapid recovery. She began to menstruate soon after the operation, and continued to do so regularly and painlessly for about four months. Then she complained of morning sickness, nausea, cardialgia, and also abdominal enlargement. An examination

showed that she was pregnant. In due time she was delivered of a healthy girl. The child died two or three weeks after birth, and soon after that the patient menstruated and has continued to do so regularly and normally ever since. The only explanation Morris offers for this pregnancy after removal of both ovaries and tubes is that there may have been a third ovary or that a scrap of ovarian tissue must have been left behind. He cites a number of writers who have reported similar cases, and also a few who have found supernumerary ovaries.

Treatment of Acute Rheumatism.—Since Maclagan, in 1874, introduced the salicyl compounds in the treatment of rheumatism, the physician has possessed a most satisfactory and certain remedy and the patients' suffering has been greatly minimized. Whether this drug acts as an antiseptic, destroying the specific organism, or has an antitoxic action, or is merely a nerve sedative, is yet unknown, but its specific action is none the less certain. A. P. Luff (*Practitioner,* Jan., 1901), in reviewing the treatment of this disease, says that the salicylates must be given in large doses, twenty grains every two hours, until the acute symptoms have subsided, and then in smaller doses for at least two weeks more. The reason that relapses have apparently become more frequent is undoubtedly due to the fact that patients are allowed to get up and the drug is stopped too soon after the subsidence of the acute symptoms and before the disease has actually ceased. The treatment by alkalies was originally based upon the belief that rheumatism was a result of excessive production of lactic acid, and, although this theory is no longer held, the alkalies are still used in combination with the salicylates to diminish the tendency to hyperfibrinosis of the blood, which occurs when the alkalinity is lessened. The tendency toward endocardial complications is believed to be diminished thereby. Potassium bicarbonate, thirty grains, may be given every two hours at first and the dosage gradually cut down. The disagreeable effects of the salicylates may be largely obviated by the free use of calomel. Sodium salicylate seems to be the most efficacious preparation, but when not well tolerated salacin should be substituted. Absolute rest in bed, woolen clothing, and a fluid diet are essential. For the relief of pain in a joint, blistering, tincture of iodine, or, better still, the application of a piece of lint saturated with about a dram of salicylate of methyl, will be found very beneficial. Hyperpyrexia is not a very frequent complication since salicylates have been so freely used, but when it does occur energetic treatment by means of cold baths, cold packs, and stimulants, should be at once employed.

New Objective Test for Mastoiditis.—Albert H. Andrews (*Jour. Am. Med. Assoc.,* Jan. 26, 1901) says that the use of the stethoscope and the tuning-fork to determine the comparative density of the two mastoids is a valuable aid in the diagnosis of mastoid complications. The method he believes to be a new one. The test is made by placing a stethoscope with a small bell over the tip of the mastoid and placing the handle of a vibrating tuning-fork over the antrum. It is found that when the mastoid is filled with pus or granulations, or when it is dense from obliteration of the air-cells, the sound-waves are transmitted to the ears of the examiner more distinctly than when the same test is made on the opposite or normal side. Care must be taken not to stretch the skin between the tuning-fork and the stethoscope, for then the vibrations are heard better than when the skin is not stretched. The lower border of the middle fossa can also be very accurately located by the same method. The line indicating the change from cranial cavity to mastoid is usually well defined. The position of the lateral sinus in relation to the mastoid can be determined in the same manner, but not so accurately. The writer has found this test of use in his examinations of mastoid cases. He reports a case in detail showing the advantage of this test.

Treatment of Influenza.—After pointing out the differences in the clinical aspect of the ordinary grip attack this year, when catarrhal symptoms are so prominent, as compared with the epidemic which occurred in 1890, W. H. Thomson (*N. Y. Med. Jour.,* Jan. 26, 1901) offers the suggestion that the mildness of the recent cases has been partially due to an immunity acquired by a previous attack of this most prevalent contagious disease. To counteract the vascular derangements of the respiratory tract, aconite is a very favorite remedy in the early stages. Phenacetin seems to have a most beneficial effect upon the febrile pains and, when combined with quinine, is thought to have perhaps a true antitoxic effect upon the influenza poison. They are used not so much to reduce the temperature as to mitigate the symptoms and prevent sequelæ. A favorite prescription with the author is: Extract of aconite, gr. $\frac{1}{6}$; Dover's powder, gr. j; phenacetin, grs. iv; quinine, grs. iij, made into two pills, but given at one dose, three times a day. When nasal catarrh is a prominent symptom a pill containing an eighth of a grain of belladonna and two grains of camphor afford relief. A flushing of the throat by a Davidson syringe with a quart of hot water, containing two drams of potassium chlorate and five minims of oil of peppermint, is very grateful. Attacks of excruciating pain in the supraorbital region, with photophobia often coming on at regular intervals, is almost certainly relieved by dram-doses of fluid extract of ergot. A very troublesome complication is the presence of large quantities of viscid sputum in the bronchioles, which keeps up a futile and exhausting cough. The emulsion of linseed oil, half an ounce, with a twelfth of a grain of morphine sulphate and eight grains of chloral, has been used for years by the author as the most efficient means of liquefying a viscid mucus of the bronchi.

Leontiasis Ossea.—A case of this very unusual condition is reported by E. H. E. Stack (*Bristol Med.-Chir. Jour.*, Dec., 1900). The patient was a female, aged two years, with no important etiological history, except that when very young she received an injury to the head which required several months to heal. When about seven, the enlargement of the head was noticed and this gradually increased, being considered due to hydrocephalus. Her mental condition was remarkably good. She died suddenly of acute obstructive dyspnea due to a tumor in the nasopharynx. At autopsy the skull was found to be greatly thickened, the vault being in some places three inches. The skull weighed eight and one-half pounds and appeared to be normal in shape on its interior, none of the foramina being constricted. The brain was normal in size and appearance. There was a double scoliosis, a distorted pelvis and the femora were bent forward, but there was no enlargement of any bone except those of the skull. The liver was fatty and cirrhotic and possibly syphilitic. The thyroid contained a mass which resembled the appearance of the gland in exophthalmic goiter. No other lesions could be found.

THERAPEUTIC HINTS.

Dyspepsia Pills.

℞ Quinin. sulph.....
Ext. rhei.....
Ac. carbol. .....aa. 1.0 (gr. xv)
Pepsin ..... 5.0 (gr. lxxv)

M. ft. pil. No. XXX. Sig.: One before each meal at which meat is taken.—*Lennox Browne.*

Furunculosis.—Attend to the general health, writes Geo. T. Jackson, look for diabetes or other constitutional disease and give tonics. Among the remedies recommended are sulphide of calcium, gram 0.006 (gr. $^1/_{10}$), every two or three hours, the compound syrup of the hypophosphites, grams 8.0 (℥ ij), three times a day, sodium hyposulphite, gram 1.0 (gr. xv), three times a day, tar-water up to a quart a day, or half a wineglass of yeast night and morning. Le Gendre advises for intestinal antisepsis every four hours:

℞ Betanaphtol .....
Bism. salicyl.....
Magnes. carb.....aa. 0.3 (gr. v)

Boils should neither be poulticed nor squeezed. They may often be aborted by injecting pure carbolic acid, applying ointment of the red oxide or nitrate of mercury, or painting with iodine. If the boil is already mature, thrust a little pure carbolic acid into its central opening by means of a wooden toothpick, then dress with carbolized vaseline or boric-acid ointment. Or it may be opened and dressed with iodoform or aristol.—*Diseases of the Skin.*

Aortic Aneurism.—The remedy *par excellence*, writes H. A. Hare, is potassium iodide, gram 0.65-1.3 (gr. x-xx), three times a day, with complete rest in bed, and a non-stimulating, easily digested diet, or even an absolute milk diet. If the heart is excitable and irregular, with high arterial tension, tincture of veratrum viride, gram 0.065-0.13 (♏ j-ij), may be given two or three times a day, but no digitalis. Aconite is of less use than veratrum. Opium, morphine and chloral, or, best of all, croton-chloral may be given for pain and restlessness, as:

℞ Morph. sulph.....0.08 (gr. ⅛)
If dyspnea is marked, "whiffs" of chloroform
Croton-chloral .....0.65 (gr. x)

are useful.—*Practical Therapeutics.*

Bronchopneumonia in Infants.—In every case of bronchitis, whooping-cough, measles, scarlatina, diphtheria, etc., isolate the patient, avoid catching cold, keep nasal passages and mouth clean with boric-acid solution, and keep bowels open with calomel, says Carrière. When the bronchopneumonia has declared itself keep the patient in bed in a well-ventilated, cool room, wrap the lower limbs in cotton, and have the child's position changed often. Feed plenty of milk, bouillon and beef-juice and much water to drink. To lessen the congestion and increase the evacuation of pathological products, give syrup of ipecac, grams 4 (dram j) every five minutes till vomiting supervenes, and follow by warm water; then give every three hours a tablespoonful of the following:

℞ Ergotin ..... 0.06-1.0 (gr. j-xv)
Strych. sulph.. 0.0002-0.0005 (gr. $^1/_{300}$-$^1/_{120}$)
Syrupi ..... 20.0-40.0 (℥ v-x)
Aquæ .....ad. 120.0 (℥ iv)

And apply dry cups, mustard plasters, or poultices. Stimulate the body with warm baths or mustard baths, and with a suppository night and morning of quinine hydrobromate, gram 0.06 to 0.40 (gr. i-vij). Cleanse nasal passages with 10-per-cent. mentholated oil, the mouth with boric-acid solution, and the bronchi by the internal administration of eucalyptus, terpin hydrate, benzoate of sodium, etc. Give every day a grain of calomel for each year of age. For feeble heart give digitalis, sparteine sulphate or benzoate of caffeine; for dyspnea, inhalations of oxygen; for collapse, friction with hot flannels wet with spirit of camphor, or inject solution of camphor in oil or ether. During convalescence, give cod-liver oil or the following:

℞ Calc. lactophos..... 60.0
Calc. glycerophos..... 60.0 (aa ℥ ij)
Aquæ .....1 liter (1 quart)
—*Le Nord Médical.*

Colic With Tympanites.—

℞ Spt. aetheris comp..... 2.0 (℥ ss)
Tinct. opii camph..... 8.0 (℥ ij)
Aq. chloroformi.....30.0 (℥ i)
Aq. menth. pip.....60.0 (℥ ij)

M. Sig.: A tablespoonful every hour or two according to the severity of the attack.—*Le Progrès Médical.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, FEBRUARY 9, 1901.

THE MAJESTY OF THE LAW.

What a fine thing it must be to be a Judge and settle delicate ethical questions regardless of the prevalent opinion of humanity. Nothing need ever perturb a Judge any more than the Cardinal who was dining on a Friday at the house of a lady who had forgotten the fast of the Church. "Let all that is on this table be fish," said the Cardinal and he straightway proceeded to make a good dinner.

It has long troubled the medical profession that its members should be subpœned to appear in court, regardless of their appointments and office hours. Lawyers are not so summarily treated, but are consulted as to their convenience. Dr. Keen was once interrupted in the midst of an important operation by a process-server, but he refused to leave the operating-table as his patient's life would be endangered, and the Judge excused him.

The shortsightedness of common sense would have said, save your patient always and then go to court. But who ever heard of other witnesses being keep waiting, of a case being postponed, or a verdict delayed, or any of the terrible contingencies that might occur if a physician delayed to ease a hurt or save a life. No, a case in hand proves it. Dr. W. D. Moore of Philadelphia was late by half an hour in court, whither he had been summoned as a witness in an accident case. The Judge, we spare him the notoriety of mention, fined him ten dollars. He pleaded that he had been with a patient who was critically ill, and that he had tried to catch the train. "Well, then," said the august Judge, "because you tried to catch the train I'll take off the ten dollars, but, remember," and here let physicians note the decree, "it were better that the patient should die than that the community's witnesses should place themselves in contempt of Court."

The Biblical implication is that only "the Judge of all the earth" is infallible, therefore we must not place too much stress on the dictum of the Judge of Philadelphia; for we think that if he had been able to kick a dog or slam a door, accidentally, when he felt himself constrained to accept the doctor's excuse, he would not have loaded himself with so much responsibility concerning the ethics of medicine and the law.

DR. KEEN ON THE PROGRESS OF SURGERY IN THE NINETEENTH CENTURY.

The surgeon's art at the end of the Eighteenth Century was little more than skilful butchery; and yet the surgeon who amputated a limb or removed a cancerous breast had his heart wrung as no surgeon of to-day has by the suffering he was obliged to inflict to save life, and by the uncertainty of the success of his operation. To-day the suffering and the uncertainty are reduced to a minimum through the discovery of anesthesia and antisepsis; with the result that the skilled speed that was once so necessary to shorten the agony of the knife is now replaced by the deliberate skill required in minute dissections, and the ever-present dangers of blood-poisoning, erysipelas and gangrene are banished by the knowledge of the bacteria that cause them.

Dr. Keen, in his very comprehensive and critical history of the Progress of Surgery During the Nineteenth Century, published in the *New York Sun* of Sunday February 3d, traces the great factors that have revolutionized this branch of medicine, and it is with a feeling of amazement that we wonder how such advances could have been made in so few years.

It is to the underlying sentiments and to the quiet individual work that we owe the detailed

success. The discovery of ether and chloroform was even in itself perhaps the greatest complete discovery, but the exploding of the theory of spontaneous generation and the proof of the resistance of bacteria by Pasteur, with the discovery of antisepsis by Lister, were but the beginning of endless experiments made by patient laboratory workers on countless of the prolific lower animals, and of a series of discoveries that have run every diseased tissue of the body to its origin. The interest in this resumé of surgery lies for us, therefore, not so much in the distinguished names of discoveries, but in the cooperative work of all surgeons of the world.

One of these forces has been the impetus in the study of anatomy and pathology. It is only very recently that the requisite material for such studies has been provided by law. Formerly, to steal a dead body was the only means of acquiring a cadaver. In England up to 1832 a regular traffic in human bodies existed as well as here.

Sir Astley Cooper, in his testimony before the Parliamentary Committee made a shiver run down the backs of the noble lords by saying that in order to dissect the body of any of them it was only necessary for him to pay enough. As a result of the atrocities that were perpetrated in order to acquire sufficient material, the laws in England and of most of the States have made it possible to obtain a reasonable number of cadavers.

Another cause and effect of increased skill in operations is the invention of instruments of precision which ingenious surgeons of every land have contributed to the science and an equal factor has been the constant interchange of methods by surgeons by means of the medical journals that have increased with such astounding rapidity during the last twenty-five years. Prior to the last few decades there were a few celebrated men to whom people came for major operations all over the country. An Astley or a Pancoast was himself the genius that made a difficult operation successful in past decades; to-day it is applied technic or the collaborated results of the work of different men. Willard Parker's operation for abscess above the groin, the precise significance of McBurney's point, these and other new ideas have been spread over the whole civilized world by means of the literature, and now, after twenty years, there is probably not a city in the United States in which some surgeon has not performed successfully the operation of appendicitis.

Operations on the stomach, the kidneys, the lungs, the heart and the brain, the organs that were heretofore considered impossible to touch, are every day becoming more common; and not only are these done by the few celebrated surgeons who have devised them, but by the internes in hospitals and the young men of the country.

With the Roentgen ray illuminating one's very bones, and the application of spinal anesthesia, the new century has dawned with vast possibilities; and Dr. Keen states that marvelous as has been the advances of surgery in the Nineteenth Century, especially in the last thirty years, he believes that still more wonderful things lie hidden in the realms of surgery that the Twentieth Century will reveal.

REPORT ON ANESTHETICS OF THE BRITISH MEDICAL ASSOCIATION.

The long-promised report of the Anesthetics Committee of the British Medical Association is an important document, as might have been expected from the time and trouble spent in its preparation. The material upon which it is based was collected in 1893. But the detailed examination and classification of the 25,920 recorded cases have required much time and trouble. Upward of 800 cases have been printed with all available details and give examples of almost all the varieties of complications.

Excluding other causes than the anesthetic, chloroform was responsible for more than one case of danger in every 200 administrations, ether for less than one in 1,500, gas and ether for less than one in 1,000. One conclusion is that a mixture containing chloroform should not be administered by means of a closed inhaler. It is especially in cases of good general health that chloroform is so much more dangerous than other anesthetics while ether is singularly safe.

As the gravity of the patient's condition increases anesthetics become progressively more dangerous. The dangers of chloroform and ether are much alike in extreme conditions. The tendency for circulating complications to appear increases directly with the length of the administration and amount of chloroform employed. Respiratory complications are of equal frequency under ether and chloroform, but under the former are trifling and transitory; under the latter grave and persistent.

One of the objects of the Committee was to examine from a clinical standpoint the statement

of the Hyderabad Commission that chloroform has no direct action on the heart which has given rise to very heated controversy between pharmacologists and physiologists of such repute as Sir Lauder Brunton (who was a member of the Commission) and Dr. Leonard Hill. So far as clinical evidence goes this conclusion is repeatedly refuted. The Committee find that "when danger occurs under chloroform, whatever its exact nature may be, there is abundant evidence that in a large proportion of cases the symptoms are those of primary circulatory failure." Another conclusion is that by far the most important factor in the safety of anesthetics is the administrator; the greater his experience the safer the administration.

ECHOES AND NEWS.

NEW YORK.

Lectures on Toxic Neuroses.—Dr. T. D. Crothers of Hartford, Conn., will deliver a course of clinical lectures "On the Neuroses and Psychoses of Spirit and Drug Diseases" at the hall of the New York School of Clinical Medicine, 328 West 42d Street, New York City. The first lecture will be given February 18th at 8 p. m. The profession is cordially invited to attend.

Harvard Medical Society of New York City.—At the last meeting of the Society, held at the University Club, the following officers were elected for the year 1901: President, Dr. Howard Lilienthal; Vice-President, Dr. Theodore W. Dunham; Secretary, Dr. J. Hilton Waterman; Treasurer, Dr. Joseph Kenefick.

State Death-Rate.—The number of deaths from all causes reported for the year to the State Board of Health is 128,468. This exceeds the mortality of 1899 by 6,647 and the average of the past five years by 8,000. Besides these reported deaths there were 1,600 returned too late for report, making the death-rate for the year 18.5. The increase over last year is largest in the maritime district, where there were 5,600 more deaths than in 1899. The infant mortality was 4,000 greater than last year, but the percentage of deaths under five years is the average of past years. Typhoid fever was unusually prevalent in the autumn, causing 1,948 deaths, 350 above the average. Measles prevailed to excess in all parts of the State, the 1,333 deaths being 300 above the average. Scarlet fever was less than usually prevalent. Diphtheria had a mortality 500 below the average. Smallpox was brought from outside to seventeen places during the first half of the year, without spread. From August to November the State was free from it; then a traveling minstrel troupe left it at three localities in the eastern part of the State, whence it spread. Of fourteen deaths, four have occurred outside New York City. The grip epidemic of the year was unusually severe, and probably added 1,500 to the number of deaths.

New Dobbs Ferry Hospital.—The Dobbs Ferry Hospital Association has decided to have a hospital which will be an architectural ornament to the village. It will, probably, be of one story only, built of brick.

Cancer Home for Men.—An attempt is to be made to secure funds by which the ministrations some time exercised by St. Rose's Free Home for Incurable Cancer, but only for women, may be extended to the cases of destitute men. It is intended to establish a second home near the first, in Cherry Street, the new one to be under the supervision of the Dominican Sisters, and to be known as St. Joseph's Home. The sum of $40,000 is needed, and George Warrington Curtis has given $2,000.

PHILADELPHIA.

Pennsylvania Raises Medical Standard.—The University of Pennsylvania, at the beginning of the present school year, adopted a curriculum embodying four years of exclusively medical study. This new curriculum has just been adopted by the State Medical Council, at its winter meeting, as the standard for Pennsylvania. Under this new standard it is impossible for an unfit man to secure the right to practise medicine in the State.

Compulsory Vaccination.—The case of Charles J. Field against the Principal of Keystone Public School, has been appealed to the Supreme Court, the lower Court having sustained the teacher who refused admittance to the daughter of Mr. Field, she not having been vaccinated. Decision of the Court is reserved. The Anti-Compulsory Vaccination League has sent to Harrisburg a petition for the repeal of the objectionable features of the law.

Appointment of Dr. McFarland.—Dr. Joseph F. McFarland has been chosen by the well-known firm of Parke, Davis and Company as pathologist and bacteriologist.

County Medical Society.—At the meeting of January 23d, Dr. Albert E. Roussel reported three cases of malignant endocarditis, one following measles, a second following a typical attack of typhoid fever, and a third terminating in recovery. The second case, owing to enlargement of the spleen and superficial glands and the condition of the blood, simulated leucemia. Recovery in the third case would seem to throw doubt on the diagnosis, but several facts were regarded as proof of its existence, *viz.*: The patient had shortly before been accepted for life insurance; the blood, as well as numerous abscesses contained streptococci; lesions of the heart have persisted, as proven by murmurs. Dr. J. M. Anders stated that visceral and cutaneous embolisms were the most important diagnostic points in the disease. Dr. John B.

Roberts reported two cases of epiplopexy for cirrhosis of the liver. Both patients died, one in six months, the other the day following operation. The true value of this procedure has not yet been determined, but as it is a trivial one Dr. Roberts believes it should be done as soon as the diagnosis is made. The technic he employs is as follows: An incision through the abdominal wall above the umbilicus is made under local anesthesia. A finger is introduced and the omentum held against the abdominal wall. Sutures of chromicized catgut are then passed by means of a long, curved needle which enters the skin, passes through the abdominal parietes and omentum and emerges through the skin about one inch from the point of entrance. The omentum should also be anchored in the abdominal incision when it is closed.

Officers of the Society for the ensuing year are: President, Dr. Geo. Erety Shoemaker; Vice-Presidents, Drs. Thos. H. Fenton and Francis Perkins; Secretary, Dr. Elwood R. Kirby; Treasurer, Dr. C. L. Bower; Censor, Dr. Frederick P. Henry.

Symposium on Brain Tumors.—Tumors of the Brain was the subject of discussion at the meeting of the Neurological Society, January 28th. Drs. Wharton Sinkler, F. X. Dercum, J. K. Mitchell, W. G. Spiller, and C. K. Mills reported cases. Dr. Sinkler called attention to the close resemblance in some cases of the symptoms of paresis to those of brain tumor. Dr. Mills spoke of localizing symptoms in tumors of the parietal and prefrontal regions. Great importance is placed on the occurrence of the sensory symptoms before motor manifestations present themselves. In the discussion Dr. W. W. Keen spoke of the amount of injury to the brain that was inflicted in some cases. In a recent case the lateral ventricle was opened. The early recovery of motor function is noticeable, in the case mentioned the boy moving his arm and leg in forty-eight hours. One surgical problem to solve is whether to close the wound and run the risk of hemorrhage, one patient dying from this, or drain and probably have a fungus cerebri result. In the last case operated upon he left gauze drainage in for only twenty-four hours, yet a fungus cerebri is threatened. This, however, is more readily dealt with than is hemorrhage.

New Medical Journal.—It is stated that subscriptions to the stock of a new medical journal, to be owned entirely by members of the profession and edited by Dr. Geo. M. Gould, have been unexpectedly great and now ensure the founding of the journal. It will be known as *American Medicine*, and it is expected that the first number will appear during March.

CHICAGO

The Giving of Commissions and Division of Fees.—At a recent meeting of the Chicago Medical Society, held January 23d, the following resolutions which are of great interest to the profession, were presented: "*Whereas*, It is commonly reported that some consultants and operators are in the habit of compounding fees; and, *Whereas*, The giving of commissions or a part of the fees by physicians or surgeons to any other person is detrimental to the good name of the profession and reduces the practice of medicine to the lowest commercial basis: (1) Because it is in effect the employment of an individual drummer for personal advertising; (2) because it in effect promotes one's personal gains at the expense of other well-qualified physicians by an underhanded method of cutting fees; and (3) because it is in effect the practising of a confidence game upon the patient; therefore, be it *Resolved*, That this course is considered dishonorable by this Society, and shall subject any member practising it to expulsion. *Resolved*, That every member knowing or hearing of any member of the Society violating the spirit of this resolution, is hereby earnestly requested to report the same to the Committee on Judiciary, in writing, with the fullest possible circumstantial statements, to the end that the facts or rumors may be thoroughly investigated for the benefit of the accused and for the benefit of the Society. *Resolved*, That it shall be the duty of the Committee to employ every means in its power to ascertain the facts in the case; that it shall notify the accused of the charges; and shall give him every facility to explain the matter, and that it shall report its findings to this Society as soon as practicable. *Resolved*, That the wilful violation of the spirit of these resolutions after this date shall be a good and sufficient cause for expulsion from this Society, and that upon the report of the Committee upon any case a three-fourths vote of the members present, by secret ballot, shall determine the action of the Society.

Dr. J. B. Murphy endorsed the resolutions strongly. Dr. Harold N. Moyer said the sentiments of the resolutions were his own, but he felt sure that nobody in the Society would divide a surgical fee, and it was unnecessary to establish such a ruling. He was willing to recommend against the practice, but not to legislate upon it as penal in the professional code. His midway position brought the opposition from under cover. Dr. William E. Quine, although a signer of the resolutions as presented, became the champion of the general practitioner, and it is said he opposed the measure in vigorous terms as hypocritical and unjust. He is reported to have spoken as follows: "I have never taken a part of any surgeon's fee who has operated upon cases at my instance, but in the future I propose to do so. I now recognize that the matter has come to a well-defined issue and has got to be settled and, I think, in favor of giving the consultant a consideration which now is usually denied him. I think it just he should have a share of the surgeon's fee in many instances. I attended one entire family twenty years through all the vicissitudes consequent upon births, fevers, and the rounds of pains and ailments from childhood to age. Finally, one member of the household developed appendicitis. I diagnosed the case and called in a surgeon. He

got for that one operation $2,500, more than I have received before and since for my twenty years of service. I say that is not right. I now consider I was entitled to a part of the fee for my services in the case. In the future I will demand a consideration under such circumstances." The remarks of Dr. Quine elicited loud and prolonged applause. After considerable discussion, participated in by various members, for and against the resolutions, on motion they were referred to a committee composed of Drs. James H. Stowell, L. L. McArthur, N. S. Davis, Jr., Frank Billings and John B. Murphy. It is expected that the Committee will report at an early subsequent meeting.

Apropos of these resolution, the *Chicago Times-Herald*, in its issue of January 25th, publishes an editorial, a part of which we quote: "The surgeon as a preacher of ethics, as a stickler for the good name of the profession, as a contemner of the drummer and the 'commercial basis' is a sight to make gods and men weep or swear. A hint of his fitness for this role was conveyed in the declaration of Dr. Quine that the single fee of a surgeon for an operation on one of his patients amounted to more than all the fees he himself had received from that patient's family, though he had been the family physician for twenty years. The amount was $2,500, and it is $2,500 to $500 that the services were not worth the sum last named.

"Commercial basis! We have heard of a surgeon's fee recently which was large enough to constitute a very considerable mortgage on the property of the patient against whom it was charged. It was preposterous by comparison with the work done, outrageous in consideration of the victim's ability to pay. No, the basis was not commercial, it was 'banditical,' so to speak, and the scalpel was its very proper symbol. The doctor who acts as a drummer for surgeons is *particeps criminis*, and between the two the word 'operation' has come to be repeated with a sinister monotony. An honorable doctor may grumble at the surgeon's fee, but he will have no division. In every necessary case whatever pay is given should go to the man who performs the work."

Dr. Quine says that he has been misquoted in relation to this question, probably because he himself did not state his position very clearly in the debate.

The position of Dr. G. Frank Lydston on this subject is very timely and unmistakable. He says: "If the practice of medicine is merely a trade, it is time the fact was understood. Reputable physicians are supposed to be on the same professional plane. If one man regards his practice as a trade and acts accordingly while another regards it as a noble profession, the two are widely apart and should not, even theoretically, occupy the same plane. If the paying and receiving of commissions by physicians is right, then all of our claims to recognition as a learned profession should be thrown to the winds. A profession which ostracizes a doctor who advertises in the newspapers, yet fraternally recognizes a man who gives and receives commissions for steering cases to him is a spectacle for gods and men. Suppose, for the sake of illustration, that the family physician should refer you to me for the performance of an operation; I perform it, and, if you are a man of means, I charge you $1,000 for it. You subsequently ascertain that $500 of this was surreptitiously paid by me to your family physician. Would you not doubt the honesty of the whole transaction? Would you not wonder whether your doctor had referred you to me for your own good or for what there was in it? Would you not wonder whether the operation was really necessary or not?"

Resolutions Condemning the Giving of Division of Fees.—The Committee to which were referred the resolutions introduced at a meeting of the Chicago Medical Society on January 23d made the following report at a meeting held January 30th: *Resolved*, That the offering or giving of a commission, or percentage of a fee, by the consulting physician or operating surgeon, or the asking or receiving of such a fee or commission in any guise whatsoever by the physician referring the case, is dishonest, disreputable and unethical, unless such an arrangement be made with the full knowledge of the patient. *Resolved*, Further, That a violation of this resolution shall subject the offender to expulsion from the Society. These resolutions were unanimously adopted by a rising vote. Dr. Archibald Church introduced the following resolution: That it be the sense of the Society, that the fees ordinarily received by the attending physician in connection with cases requiring surgical operations in common practice are not adequate, and that the physician should have the support of the Society to increase his charges under such circumstances. This resolution was likewise adopted.

County Hospital Medical and Surgical Staffs.—President Hanberg recently submitted a recommendation to increase the number of internes at the County Hospital to 39, of whom 27 shall belong to the regular school, 7 to the homeopathic, and 5 to the electic. He urged also that the hospital staff be divided into three classes, to be known as the attending staff, the associate attending staff, and the advisory staff. The associate attending staff is to furnish substitutes for the attending staff, while the advisory staff is not to be called upon unless the work becomes too great for both of the other staffs to attend to properly. The list of appointees is as follows: *Surgeons*, Drs. J. B. Murphy, T. A. Davis, Denslow Lewis, F. S. Hartmann, Charles F. Swan, John Leeming, E. L. Moorhead, A. I. Bouffleur, Leonard St. John, S. L. Weber, J. W. Tope, Charles Davison, C. P. Stringfield, Weller Van Hook, Daniel H. Williams, F. W. McNamara, Aime P. Heineck, O. W. MacKellar, D. N. Eisendrath, W. E. Schroeder, Frank Byrnes, G. Seim, A. E. Halstead, W. A. Kuflewski, J. P. Webster, H. R. Hammond, R. A. Letourneau, T. J. Conley, and M. J. Kearsley. *Attending Physicians*, Drs. Frank Billings, Arthur R. Edwards, James B. Her-

rick, Chas. C. O'Byrne, E. Fletcher Ingals, William E. Quine, B. M. Linnell, John A. Robison, Florence Hunt, T. A. Noble, J. F. Dolamore, and A. E. Price. *Pathologists,* Drs. L. Hektoen, and W. A. Evans. *Dermatologists,* Drs. L. Blake Baldwin and M. B. Sincere. *Obstetricians,* Drs. Effie L. Lobdell and Frank B. Earle. *Diseases of Children,* Drs. F. S. Churchill, Josephine A. Jackson, Wm. J. Butler, and Isaac Abt. *Ophthalmologists,* Drs. Allen T. Haight and J. C. Huizinga. *Nervous Diseases,* Drs. Sanger Brown and D. R. Brower. *Dental Surgeon,* Dr. Hart J. Goslee.

Chicago Medical Examiners' Association.—At its January meeting the following officers were elected: President, Dr. Denslow Lewis; Vice-President, Dr. James E. Stubbs; Secretary, Dr. James H. Stowell; Treasurer, Dr. J. Homer Coulter.

Three Cases of Acromegaly.—At the meeting of the Chicago Neurological Society, held January 11th, Dr. Sydney Kuh reported three cases of acromegaly treated with pituitary bodies. In the first case the existing headache and mental depression seemed somewhat relieved, while in the other two cases the patients were benefited to a more marked degree; headache, vertigo, general weakness, hyperidrosis and projectile vomiting ceased, and in one instance trophic disturbances in the nails of the hands showed well-marked changes for the better. In the third case cramps in the calves of the legs appeared after the patient had been under treatment for nearly one and a half years and the woman became very much depressed mentally. The essayist said that he did not believe the results to be due to suggestion only. He believes that the disease of the pituitary body is the cause of acromegaly. In every case of this malady in which a thorough postmortem examination was made, the gland was found to be affected not only in man, but also in the one case known to have occurred in an animal. There is a good deal of evidence to show that the hypophysis exerts some influence upon our physical development, that it may not only cause acromegaly, but under certain conditions the opposite condition, stunted growth.

Internes in Asylums.—Four of the city medical societies have passed resolutions recommending the selection of at least four medical internes for each of the State hospitals for the insane; that such internes shall be selected by competitive examinations from the graduates of the medical colleges in the State, recognized by the State Board of Health; that they shall serve for one year, and receive as compensation lodging, board, washing, and $100 at the expiration of their term of service, and that the professors of nervous and mental diseases of the five medical colleges having the largest number of students in attendance shall be the examiners to select these internes.

Professional and Unprofessional Advertising.—This subject was dealt with by Dr. G. Frank Lydston at the Physicians' Club of Chicago. This paper will appear in the Medical News.

Practice of Medicine as a Source of Income.—Dr. A. K. Steele read a paper on this subject, in which he said that there is a vast amount of ignorance on the part of the public, and of the profession as well, which is usually rudely dispelled when the dead doctor's will is made public in the Probate Court, and general surprise is expressed that Dr. A., who was reputed to have an income of from $20,000 to $30,000 a year, left his family only a ten-thousand-dollar estate, and had allowed his life insurance to lapse a few months before his death. The speaker said he had taken pains to ascertain the average income of doctors from their practice, and he is firmly convinced that professional incomes are greatly over-estimated. The expenses of the physician keep pace with his increasing business. Larger incomes demand better offices, a finer house, more servants, more social duties, and at the end of the year the balance sheet shows very little on the side of net profit. The two- to three-dollar visit, the five- to twenty-five-dollar consultation, the ten- to thirty-dollar case of obstetrics, and the larger fees provided for operative work in the fee table do not insure large incomes for many in the profession. The first five or ten years' practice is usually a struggle for existence; the second ten years' a competency, or good living, and during the third ten years the physician is likely to be crowded out by the younger and more progressive element. He said one could count on the fingers of one hand the practitioners in Chicago whose incomes from practice exceeded $30,000 per annum, and probably not more than a score exceeded $20,000 per annum. The income of the average practitioner varies from $1,500 to $3,000 per annum. Office specialists—eye and ear, nose and throat—average $2,000 to $6,000; consulting physicians, $5,000 to $15,000; six leading physicians, $15,000 to $35,000; six leading surgeons, $20,000 to $60,000; six leading gynecologists, $10,000 to $20,000; six leading office specialists, $10,000 to $15,000; average surgeons, $3,000 to $10,000. One's income may be enhanced in a variety of ways, as, for example, increasing his reputation by original work; by essays and discussions in medical societies; by affiliation with medical colleges in a teaching capacity; by becoming attached to the staff of a reputable hospital; by caring for the sick or injured of a corporation; by making life-insurance examinations. It is perfectly legitimate to build up a practice in this way. Practice may be increased illegitimately by criminal curettements, by unnecessary operating, by useless visits, by exploiting cases in the public newspapers, by specialists' reprints for patients, by lending one's name to endorsement of proprietary remedies, etc.

Legitimate and Illegitimate Fees.—This phase of the subject was discussed by Dr. A. J. Ochsner. Dr. A. H. Ferguson offered the following resolution, which was adopted: *Resolved,* That the Physicians' Club of Chicago most severely condemns the asking for or the receiving of a commission or part of a consultation or

operation fee, as well as the offering or giving of a commission, or a part of a fee, as practices highly dishonorable and detrimental to the best interests of the medical profession.

Organization of the Cook County Hospital Staff.—At the annual meeting of the Cook County Hospital staff, held January 31st, Dr. Denslow Lewis was re-elected President, and Dr. L. Blake Baldwin was re-elected Secretary. The following executive committee was appointed by the President: Drs. Arthur R. Edwards, James B. Herrick, William E. Quine, J. P. Webster, C. P. Swan, O. W. MacKellar, and M. J. Kearsley.

Railroad Surgeon.—Dr. W. H. Hutchings of Ann Arbor, Michigan, has been appointed Chief Surgeon of Ann Arbor Railroad to succeed Dr. W. J. Herdman.

GENERAL.

Medical Examination Before Marriage.—A marriage license bill was introduced in the Wisconsin Senate January 16th which promises to eclipse the marriage law of 1899. This bill provides that no persons can marry who are suffering from true or hereditary insanity, insanity caused by vicious habits or the use of drugs, consumption and various other diseases which are named in the bill. Every person who wishes to marry is required to go before an examining board of three surgeons to be appointed in each county of the State by the county Judge, and must pass an examination before a marriage license can be issued to them. In addition all male candidates for matrimony who are under twenty-five years of age and all female candidates under eighteen years must produce a written consent of their parents before they can secure a license. Any clergyman, Justice of the Peace or other person who can perform marriages and who marries any couples who do not produce a certificate from the examining physicians of his county is to be fined not more than $500 or confined in prison not more than one year.

Plague at Cardiff.—It is officially certified that a mill worker at Cardiff, Wales, is suffering with bubonic plague. Another mill-hand is suspected of having the disease.

Plague at Constantinople.—Advices from the Marine Hospital Reports show that the plague has again broken out in this city.

St. Louis City Hospital Alumni.—At the annual meeting of the Medical Society of City Hospital Alumni, held December 20th, 1900, the following officers were elected for the ensuing year: President, Dr. Norvelle Wallace Sharpe; Vice-President, Dr. Francis L. Reder; Secretary, Dr. John Green, Jr.; Treasurer, Dr. Horace W. Soper.

Obituary.—Dr. Theodore De Clermont Miller died at his home, No. 49 West 117th Street, on Monday night last from pneumonia, after an illness of three days. Dr. Miller was fifty-nine years old and had been a practising physician in this city for thirty-two years. He is survived by a widow and three children.

Dr. Frederick S. Nelson, of New Market, N. J., died Sunday last from pulmonary troubles. He was thirty-seven years old and was graduated from Rutgers College in 1882 and subsequently took a course at the University of the South, at Suwanee, Tenn.

Dr. Henry J. Herrick, a widely-known physician and surgeon of Cleveland, Ohio, died last week. He was for many years connected with the medical department of the Western Reserve University. He was a member of the Loyal Legion, and served as surgeon general of the Ohio National Guard during Governor Foraker's administration.

Dr. Henry F. Baxter, one of the best-known physicians in the southern section of Philadelphia, died February 1st after a prolonged illness. Dr. Baxter was a man of wide culture, both literary and scientific, and was prominent in local and national chess circles.

CORRESPONDENCE.

STATE MEDICINE BILL.

To the Editor of the Medical News:

Dear Sir: The profession must know, of course, that a bill has been introduced in the Legislature of this State, the purpose of which is to enable those who are empowered to do so to enforce the medical laws. As at present interpreted these laws can only be enforced against illegal practitioners who give medicines. If a person desires to evade these laws all it is necessary to do is to adopt some peculiar name or title, as Christian Scientist, Osteopath, Hydropath, Faith-Curist, or even no name, refuse to give medicines or drugs, and, although he or she may treat disease, there has been, as yet, no lawyer who will advise action against such an illegal practitioner. The law as at present enforced is an incentive to uneducated people to adopt some of these peculiar names or methods, and they can prey upon the community with impunity and without molestation.

The bill under consideration was objected to in the beginning by manufacturers of proprietary articles, opticians, and others, who claimed that its enactment would prevent a person recommending a friend to take a dose of pepsin, or some equally simple remedy, and would interfere with the sale of patented articles and in this way interfere with the newspapers advertising such articles.

The framers of the bill had no such intention in drawing this measure, and agreed to alter its phraseology. This has been done and as the bill reads now, it declares that any person shall be regarded as practising medicine who shall give treatment to any other person, by any method whatsoever, for the relief or cure of disease, ex-

cepting in an emergency. There can be no valid objection to this bill on the part of patent-medicine manufacturers, wholesale or retail druggists, truss- or instrument-makers, or any other person who does not make a business of treating disease. Retail druggists have no right now to treat disease, except in an emergency, and this bill will not alter their position, or curtail their rights and privileges in any way. The legitimate business of the optician will not be interfered with in any way. This bill is designed to give an increased protection to the public, which is the only reason for the existence of any medical laws.

Christian Scientists, Osteopaths, and others will have to comply with the law, after which they can continue their peculiar methods if they can find any person who believes in them, or if they believe in them themselves, after they have been taught to discriminate. There is no desire to interfere with free thought or religious liberty. There is no desire to prevent any person practising any method their intelligence tells them is the best method. We only insist that every person who treats disease shall demonstrate to the State Board of Medical Examiners their ability to tell whether a disease exists, how to differentiate the disease which may exist, and then the matter of treatment must be left to individual judgment.

The battle is on and will be won by those who believe in protecting the community, if all who so believe will write to Hon. Nelson H. Henry, Chairman of the Assembly Committee on Public Health, giving their names and addresses, and urging the enactment of the bill. Will you not urge your readers to do this?

Frank Van Fleet, M.D.,
Chairman, Committee on Legislation, Medical Society of the State of New York.
New York February 2, 1901.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, January 26, 1901.

THE EPIDEMIC OF ARSENICAL POISONING FROM BEER-DRINKING—APPOINTMENT OF A ROYAL COMMISSION—HOW THE CAUSE OF THE EPIDEMIC WAS DISCOVERED BY DR. REYNOLDS—SOME OF ITS FEATURES—ARSENICAL POISON IN LIVERPOOL—DEATH FROM DIVER'S PARALYSIS—INCREASE OF LUNACY IN THE UNITED KINGDOM—THE PREPARATIONS FOR THE COMING CENSUS—DEATH DURING TOOTH-EXTRACTION UNDER NITROUS OXIDE AND ETHER FROM IMPACTION OF A PIECE OF SPONGE IN THE LARYNX—THE DANGER OF THE ADMINISTRATION OF ANESTHETICS BY DENTISTS.

A Royal Commission has been appointed by the Government to investigate the epidemic of arsenical poisoning due to beer-drinking. The Commissioners are Lord Kelvin, Sir W. Hart Dyke, Sir W. S. Church (President of the Royal College of Physicians), Prof. T. E. Thorpe (Government Analyst), Mr. H. Cosmo Bonsor and Dr. B. A. Whitelegge (Chief Inspector of Factories). Dr. G. S. Buchanan, one of the Medical Inspectors of the Local Government Board, is the secretary of the Commission. The instructions of the Commissioners are to ascertain: (1) The amount of recent exceptional sickness and death attributable to arsenical poisoning. (2) Whether it has been due to arsenic in beer or in other articles of diet. (3) In what way these articles became poisoned. (4) By what safeguards can such poisoning be prevented.

As to the manner in which the arsenic got into the beer the evidence given by the chairman of the company from which the firm who supplied the brewers with the contaminated sugars obtained sulphuric acid for the production of the latter from starch, is of interest. He said that his firm made the acid from pyrites. He had not the slightest idea what the sugar manufacturers wanted the acid for. He knew that acid made from pyrites frequently contained arsenic. They took measures to remove it, but sometimes they sold acid without doing so. The difference in price between arsenic-free sulphuric acid and non-free acid was only half a dollar per ton, sometimes less.

At the Royal Medical and Chirurgical Society Dr. Reynolds of Manchester, to whom is due the credit of discovering that arsenic in beer was the cause of the epidemic of peripheral neuritis in that town, read a most important paper. His attention was first drawn to the subject in June, 1899, when he noticed an unusual number of cases of skin eruption in the workhouse infirmary, amongst which were about six cases of erythromelalgia. Later he observed an unusual number of cases of peripheral neuritis. He then noticed that the eruptions (which included herpes) occurred in patients suffering from neuritis. Remembering that herpes might be produced by arsenic he suspected the beer, which was the apparent cause of the neuritis. Erythromelalgia—painful red swelling of the hands and feet—was perhaps the commonest eruption. The erythema was most intense at the edges, the center of the palms being almost exempt. The pain was so marked that the patients could not sleep. The red patches were followed by keratosis of the hands and feet, the scales being exfoliated so plentifully that a two-ounce bottle could be filled in a short time. This keratosis was a most important symptom in diagnosis, because fair-haired persons did not get pigmentation. There were also scarlatiniform and morbiliform eruptions. The mental condition was very peculiar, being characterized by loss of memory and power to initiate ideas. The heart was very seriously affected. It might become dilated with edema of the feet and of the chest-wall. Death usually resulted from some form of cardiac failure. The urine in many cases contained arsenic, which could be found as long as two weeks after ceasing to take the contaminated beer. In some cases there was pyrexia.

In Liverpool the city analyst's report for the last quarter shows that of 208 samples of beer examined 25 contained a trace of arsenic; 20, a small quantity; 4, 1½ grains per gallon; 2, ¾ grain

per gallon and 1, ½ grain per gallon. Four more cases of arsenical poisoning were admitted to hospital in the last weeks.

A diver has met his death in sinking an artesian well for a London water company. He was a man, aged thirty-seven years, who went down three times into the well before dinner. After dinner he went down again and came up in a quarter of an hour. While his boots were being removed he complained of giddiness and became very pale. He was put into a warm bath. He soon became unconscious. A doctor who was called in found the man suffering from dyspnea, with dusky face. His pulse was rapid and feeble and his limbs were limp. He died the same night. The necropsy showed congestion of the spinal cord. The cause of death was the severe nervous disturbance caused by passage from a pressure of 3 atmospheres to the normal—diver's paralysis.

Dr. Stewart, Deputy Medical Superintendent of the Glamorgan County Asylums, maintains in a recent lecture that lunacy is increasing—a fact on which I have previously commented. In 1891 there were 136,000 lunatics in the United Kingdom, of which 106,000 were maintained in asylums at an annual cost of $8,500,000. In 1859 there were 19 lunatics to every 10,000 people; in 1895, 40. Sixty people are now sent to asylums every day. The sanest country is England, then Scotland, then Ireland. Where there is chronic poverty, lunacy is greatest. It is remarkable that lunacy occurs chiefly in rural and agricultural districts, and still more so that the most drunken counties are the sanest. In different occupations the lunacy rate per 10,000 is as follows: Miners, 4.5; clergy and travelers, 12; farmers, 5; doctors, and charwomen, 15; domestic servants, 11.

Elaborate preparations have been made for the forthcoming census of the United Kingdom which will be taken on March 31st. These have been in progress more than a year. More than 2,000 local registrars have been appointed. Under each of these is a number of enumerators whose divisions are so planned that each includes about 300 families or 1,500 persons. In England and Wales, with a population of about 32,000,000, if each enumerator dealt with 1,000 persons, 32,000 would be required, but the cases of sparsely-populated parishes in which this number cannot be undertaken are so numerous that it is estimated that 40,000 enumerators will be required. After each registrar has completed his "plan" he will send it to a superintendent registrar. Of these there are 635. These officers after careful revision and correction will send the plans to the Government offices at Somerset House. Here they will again be subjected to a rigid examination in order to ascertain that each district is complete in itself, of suitable size, has no confusion of areas, and has a simple walking boundary which cannot be mistaken. The duty of the enumerator is to leave a schedule for every occupier of a house. On April 1st he will collect the schedules and help occupiers with advice. Between April 1st and 8th he has to copy every particular from the schedules into an enumeration book and to make certain summations. Between April 8th and 22d the registrars have to check and revise the work of the enumerators. The books will then be passed on to the superintendent registrars who have to satisfy themselves that the work has been properly done, and forward the books to the Census Office by April 27th. The headquarters staff will amount to 200 and will consist of civil-service clerks.

A unfortunate fatality has occurred during the administration of an anesthetic by a dentist. A healthy miner went to have eleven teeth extracted. The dentist administered nitrous oxide and ether, a nurse only being present. The teeth were successfully removed and sponges without attachment outside the mouth were used to press on the gums to check hemorrhage. The man sat listlessly in the chair for two or three minutes after the operation, then sprang to his feet, drew a deep breath, and gasped for air. As signs of asphyxia were evident, the dentist felt digitally for an obstruction and finding none commenced artificial respiration. Death ensued. At the necropsy a piece of sponge was found below the vocal cords. Commenting on this case *The Lancet* insists on the desirability of two medical men being present even when only a trifling operation has to be performed under an anesthetic. When the operator is a dentist it is even more necessary that a doctor should give the anesthetic. Further, in every case in which an anesthetic is given tracheotomy or some other operation of emergency may be necessary. A dentist is not competent to perform such. Hence a medical man should always be present. Tracheotomy might have saved life in this case.

ETIOLOGY OF CARCINOMA—GONORRHEAL ARTHRITIS—TRAUMATIC CARDIAC DILATATION—POSTOPERATIVE TETANUS—TRAUMATIC LACERATION OF THE CARDIAC VALVES—METHYL BLUE AND RENAL ACTIVITY—MYELOMA AND ALBUMOSURIA—REYNAUD'S DISEASE—COMPENSATION IN ATAXIA—RUPTURE OF THE SPLEEN—ALBUMIN AND ACETONE—LUMBAR HERNIA—HYPOPHYSIS CEREBRI AND ACROMEGALY—SEQUELÆ OF PERTUSSIS—NASAL POLYPI AND THEIR EFFECT ON THE NASAL BONES—OBTURATORS AND THE ANTRUM OF HIGHMORE—ACUTE GONORRHEAL MYELITIS.

Von Leyden, at the Gesellschaft der Charite-Aerzte in Berlin, November 8, 1900, exhibited various preparations and specimens of carcinoma and discussed the germ-theory of the cause of these neoplasms. The establishment of such a hypothesis rests on the results of inoculation (Klebs, Hanan and others) and on the discovery of a microscopical parasite. The latter point has already been carefully studied, as, for example, by Scheurlen, Schueller, Leopold (Blastomycetes) and by the author himself, who, in an example of carcinoma of the abdomen, in the ascitic fluid found moving

cells with active processes which in common with Schaudim he considers amebæ. His experiments to obtain cultures from sections of the neoplasm have given no satisfactory results, beyond affording a good opportunity of studying the amebæ. From the type of movement and from the peculiarities of the pulsation of the vacuole they present no diagnostic features, but they appear to be definitely recognizable from their nuclei which may be compared to a bird's eye, through having a dark central spot surrounded by a bright band and then by a dark band. These amebæ are without demonstrable capsules, but lie as naked masses in the protoplasm of the cells, from which they are with great difficulty distinguishable. The author claims that through fixation, oxidation with peroxide of hydrogen, staining with saffranin, methyl violet and orange G., he has been able to prove the presence of these amebæ in the cells of carcinoma also. They are analogous to the sporozoa (plasmodiophora) discovered by Russian investigation as causing various conditions in the cabbage, and they occur in the cell-bodies close to the nucleus which itself shows no evidence of degeneration or division. From the pictures presented by various preparations, which he claims are ameba-like protozoa, he seeks to make them analogous to the plasmodiophora and regards them as the cause of cancer.

Laqueur, at the meeting of November 22d, brought forward a young girl with gonorrheal arthritis of the right elbow. In the exudate many cocci were found. Rapid cure followed faithful use of the hot-air bath method.

Strauss reported a case of a young adult who in 1900 passed through an attack of the grip and soon after that received a trauma in the cardiac region, promptly followed by considerable dilatation of the heart, especially to the left. Bodily exertion increased it. The chief symptom was dyspnea. The valves were intact. In the discussion Brandenburg spoke of one of his patients who went through a similar experience with a cardiac neurosis. Oestreich considered it would be difficult to demonstrate a direct connection between the trauma and the cardiac lesion.

Menzer gave notes on a case of tetanus after a gynecological operation. A vaginofixation, notwithstanding most careful preliminary and operative antisepsis, was followed in seven days by a fatal tetanus. In the secretion of the wound the bacilli of tetanus were abundant. Blumenthal, discussing the subject, advocated the regular injection of anti-tetanic blood-serum before every operation upon the female genitals. In the French colonial forces such prophylactic procedure among the wounded had proved very efficacious. Jacob added that dural infusion is better than the subcutaneous.

F. Strassmann, at the Verein für innere Medicin in Berlin, November 19th, detailed the autopsy of a case of traumatic laceration of one of the aortic valve cusps. R. Stern recently stated in his new work that well-established cases of traumatic tears in the valves of the heart are not known, whereas the French authors state just the opposite. Moreover they teach that compensation for the error due to the valve leakage can scarcely occur and that therefore death usually follows very soon upon the lesion. Therefore any case of proved traumatic damage to the valves is of great value. In this instance it is a pity that more is not known of the course of the condition. The patient was a hostler, sixty-five years old, always in very good health, without known cardiac trouble, and able to care for a stable of sixteen horses. On November 24, 1899, he was kicked in the chest and in the left forearm by one of the animals. Two months later his physician discovered an insufficiency of the aortic valves, which he attributed at once to the accident; but on consultation it was decided that it was due to the lighting-up of an old endarteritis. On March 24, 1900, he died. An inquest showed a break in the ribs over the right chest and its cardiac area where the cartilages join the ribs. The two leaves of the pericardium were fully adherent. The heart, especially to the left, was much enlarged, In the first part of the aorta was a transverse tear about two centimeters long, corresponding with the situs of the valves, and involving the intima completely and the media partially. In the valve cusp, over this tear, was a laceration which extended from one border to the base and turning angularly upon itself almost to the other border. There were no other changes in this or the other cusps, except that the one next over the wound in the vessel-wall was slightly adherent to the damaged valve curtain. The aorta was very little sclerosed. The blood-pressure had not been enough to cause a dissecting aneurism. A hernia in the abdominal wall also seemed to have been caused by this trauma.

Fraenkel stated in the discussion that R. Stern's position is surely not tenable, because he had himself seen a case like the above and another in which the aorta was torn off short.

Lipman-Wulf gave the results of his experiments with methyl blue as an index of the activity of the kidney function. He followed the plan of the French who had sought to establish the fact that the rate of excretion of the blue in the urine, after hypodermatic exhibition, is the guide to the health of the organs. P. Ehrlich has recently shown that a certain proportion of the coloring matter is changed in the body to methyl white. With this observation the author agrees and concludes that the method is not at all reliable as showing the state of the kidneys.

Kalischer, at the meeting of November 26th, presented the ribs of a woman dead of myeloma and albumosuria. She was sixty-two years old and had been sick for about sixteen months. One of four daughters had died of pernicious anemia. The onset was with pain in the left, later the right side too, at first spasmodic like neuralgia, later continuous. Diagnosis, hysteria. The pains increased. For a year she had been confined to the house and for three months to bed. Albuminuria was now present. At this time Kalischer first saw her and found tenderness along the lower rib and con-

cluded that he was dealing with some hysterical or neurasthenic manifestation. Continued emaciation and prostration were apparent. Further test of the urine showed that it contained albumose, namely, that the cloudiness or precipitate on boiling disappeared if boiled still more. Then another examination of the ribs showed that the ribs were soft, unduly bendable and prominent, and that the scapulæ and sternum were thickened. Blood tests showed a slight leucocytosis, nothing else. A partial section revealed prominence of the ribs, thinning of their walls, increase of their medullary canal, red marrow of semifluid consistence and inclined to flow out of the medullary space. The ribs were broken in several places. The medulla of the right humerus was normal. Microscopically the costal marrow showed only increase in the colorless elements, such as occur in myeloma. The nervous symptoms appear to have been analogous to those in carcinosis, by irritation.

Lippmann exhibited two cases of symmetrical gangrene (Reynaud). A servant-girl who was much engaged in washing and in hanging out the clothes plunged her hands into hot water while they were thoroughly chilled. Since that time cold has been well nigh unbearable, because her hands became at first livid, then blue and very painful. Occasionally small parts are cast off without secretion. The fingers are shortened, thickened, nails flat, sclerosis marked, and full flexion impossible. Röntgen rays show bone-atrophy which is most marked in the first phalanges which have nearly disappeared. The other case concerned a fifty-four-year-old woman with considerable dulling of the mental faculties, all the senses are decreased. Onset about nine months ago. This year an isolated gangrene of one finger appeared with loss of the first phalanx. This was attributed by the patient to trauma while chopping wood.

Bickel detailed his instructive experiments on dogs as to the compensation of the brain in sensory ataxia, which he made in collaboration with P. Jakob. Ataxia can be produced in dogs by division of the posterior nerve-roots (Leyden) and thereafter follows a muscular degeneration. Improvement in such conditions occurs as has been proved by Merzbacher, apparently because the other intact brain organs have an influence upon the extremities. To such belongs the Labyrinth, as the physiologist Ewald has shown (*Ewald's labyrinthtonus*. The author has himself found that if in dogs, which have had ataxia produced by cutting off the posterior nerve-roots and have then reached the stage of compensation and partial recovery, the labyrinth is extirpated, a recurrence of the ataxia appears, which is then irremediable. In a similar way other parts of the brain can act as substitutes, as, for example, the eye and certain parts of the sensory element of the brain itself, notably the sensory convolutions of the cortex, and perhaps the optic thalamus, corpora quadrigemina and cerebellum. The possibilities of the compensatory influence of the sensory cortical cells, the author in company with Jakob investigated also in dogs. They produced ataxia of the hind legs by the same method as above, namely, in the spinal canal, and then of the front legs by cutting out the appropriate regions of the brain itself. After some improvement in the former had begun. In this way various differences were noted. The discussion of this paper was postponed.

Karewsky, at the meeting of December 3d, presented a twelve-year-old girl who a year ago was crushed against a wall by a wagon and sustained thereby fracture of several ribs and peritonitis, supposed to have been due to rupture of the intestines. Conservative treatment was followed and cure apparently reached. About twelve days after her discharge she again was taken sick with left-sided abdominal pain, tenderness and swelling, with fever. All symptoms and signs pointed to a subphrenic abscess and exploration evacuated a large, foul focus in which was found the spleen ruptured entirely out of its capsule. It was thereupon ablated. Cure followed. Present examination of the blood was negative. No investigations of it had been done before.

Von Leyden exhibited the heart of a girl suddenly dead after diphtheria. In addition to the degenerations usually present in these cases, there were thrombi scattered through its walls and an embolus in the pulmonary artery.

F. Blumenthal and C. Neuberg contributed an instructive fact to the much vexed question as to whether in diabetes, carcinoma, starvation and other conditions, the acetone present cannot have its origin in albumin. These investigators have been able to make acetone out of egg-albumin experimentally. Salts of iron were the containers of the oxygen and peroxide of hydrogen was the actual source of it.

M. G. Borchardt, at the Berliner Medicinische Gesellschaft, November 29th, presented a fifteen-month-old child with well-developed lumbar hernia. Of this rare condition forty-seven have been reported in literature. Their exit is usually through the trigonum Petit, through the trigonum lumbale superius, and occasionally through other weak spots of the parietes. In the etiology traumatism plays a very important part, then pus foci, especially gravitation abscesses, and, finally, congenital defects. Seven examples of the last-named cause are on record and this makes the eighth. The child presented a large lateral swelling of variable size, but usually that of a child's head, impulse on coughing marked, completely reducible, but presenting no real hernia ring. Its contents were intestine, spleen and the left kidney. At first the mistaken diagnosis of a cold abscess was made, but the child contracted a marked bronchitis which through the incessant cough revealed the true nature of the condition. Immediate operation was contra-indicated, first because of the bad cough and second because the child is so feeble. A reduction and suitable bandage were the present treatment. Operation will be done in a few years. years.

C. Benda, in discussing the connection between lesions of the hypophysis cerebri and such diseases as cretinism and acromegaly, stated that he

had examined its normal and pathological anatomy at length. By means of new staining methods he has discovered small granules in the cell bodies of the organ, which hitherto have not been described. In a case of cretinism he has found a decrease in the number of these bodies and a somewhat similar condition in Basedow's disease. In the brain of a dwarf he found a teratoma which occupied the sella turcica and invaded the hypophysis. In four patients with acromegaly he found profound changes in the hypophysis, once an angioma and three times tumor-like aggregations of these highly granular cells. It appears to him that there is direct connection between the lesions of this cerebral organ and acromegaly.

Arnheim, at the meeting of December 5th, described a case of pertussis in a child, four years old, which in its course developed stiffness of the neck, fever, rigidity of the extremities, numbness and slowing of the pulse. These could not be connected with a contemporary chronic otitis media purulenta with perforation, and were therefore attributable to the pertussis. After the period of fever had disappeared and consciousness had been recovered, there remained a slight degree of paresis in each of the extremities. This improved somewhat until now there are distinguishable a very moderate ataxia and disturbance of the speech. The contributor holds that this is an analogue of the paresis and paralysis seen in severe diphtheria, due to toxins.

Treitel showed a man in whom the nasal bones were much spread apart and everted, through the presence of abundant, dense nasal polypi.

P. Heymann displayed an obturator which, after the evacuation, drainage and cure of an empyema of the antrum of Highmore, had been applied to close over the operation wound. The result was that a most foul empyema occurred much worse than the first. Hence such devices are dangerous.

Von Rad, at the Aerztlicher Verein in Nüremberg, March 15th, gave the following outline of a case of acute gonorrheal myetitis recently observed by him. The man was thirty-two years old, suffering from a chronic gleet and had had a soft chancre when he was infected with an unusually violent and virulent fresh attack of gonorrhea. After four days he was suddenly attacked with weakness of the lower extremities and very soon afterward with combined retention of urine and feces. November 19, 1899, physical examination revealed these conditions: Active pain, but only moderate tenderness from the fourth to the ninth dorsal vertebra; marked weakness in each lower extremity so that only with the greatest effort can the patient take a few steps and then falls; the reflexes of the soles and tendons of Achilles are normal, of the knees are much exaggerated, while those of the abdomen and cremasters are absent; the patellar clonus is absent on each side; sensory disturbances are slight, with no paresthesiæ, but with moderate confusion between the point and the head of the pin; the bladder is very greatly distended and paralysis of that viscus and of the rectum is well established; the pulse is normal; the temperature elevated; there are no disturbances of the upper extremities or of the cranial nerves. That same afternoon complete paralysis of the lower extremities set in which was proved on examination the next day. The reflexes at the knees and ankles and of the skin are abolished, except a very feeble plantar reaction; the pains in the back are absent, but severe paresthesiæ have appeared; sensibility for the stroke of brush and needle is much disturbed; the zone of these disorders extends to about a handbreath above the navel. Further were noted the persistent and absolute vesical and rectal paralysis, so that catheterism and enemata were absolutely necessary; the advent of a very active and obstinate cystitis, and of bedsores over the sacrum in spite of all care, of clonic spasms and tremors in the muscles followed by atrophy, and of the electrical reaction for degeneration. It was finally necessary to put the patient upon a water bed to keep the bed sores in check. Death followed early in 1900. No gonococci were found on lumbar puncture, but the onset makes it obvious that these germs were the source of the infection.

SOCIETY PROCEEDINGS

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held November 24, 1900.

Howard Lilienthal, M.D., Chairman *pro tem.*

Rapid Elimination of Gonococcus.—Dr. Follen Cabot read a paper describing a method for the rapid elimination of the gonococcus. He said that two things are of importance in the treatment of gonorrhea, the avoidance of complications and the elimination of the gonococcus. Much has been written and promised in recent years with regard to methods that cause an early disappearance of this micro-organism. All of the methods thus far presented seem, however, to induce complications because of a certain amount of violence that is exercised on the delicate mucous membrane of the urethra. Other methods have proved too gentle in their action and so have caused the disease to become inveterate. Dr. Cabot's method secured the disappearance of the gonococcus in from eight to ten days in seven-eighths of the cases in which it was used. In the other eighth the course of the disease did not seem to be affected either favorably or unfavorably.

Review of Methods.—One recent method that has been employed for shortening the course of gonorrhea consists in washing out the anterior urethra and then with a cotton swab through a speculum touching inflamed points with a solution of nitrate of silver. A second method was that introduced by Janney in which irrigation of the entire urethra was accomplished by securing the relaxation of the compressor muscle of the urethra and allowing the solution to find its way

into the bladder. From the bladder its subsequent ejection gives a second washing to the urethra. For a time this method seemed to promise very favorably, but it proved to be too violent for most urethræ and induced complications. A third method consisted in the use of the double-flow nozzle, the outflow of which was larger than the inflow. Observation showed, however, that once the urethra becomes distended by the irrigating fluid very little interchange takes place between the inflowing solution and the column of fluid in the urethra itself. A short circuit of the fluid is formed between the two branches of the nozzle and the column of fluid in the urethra remains almost absolutely stationery. Certainly the method is no better than an ordinary hard rubber syringe. A fourth method makes use of a soft catheter, which is inserted into the urethra while the solution flows back along the instrument to find its way out at the meatus. By this method some of the solution originally introduced remains in contact with the urethra, that is to say, friction retains a layer of solution just over the mucous membrane. In this way the gonococci just beneath the surface of the mucous membrane or lying between the cells are protected from contact with the stream of fluid and so fail to be washed out.

Gonococci and Silver Salts.—Dr. Cabot proposes a combination of the good features of these methods. For the injection, in accordance with the old tradition that makes the silver salts the best antiseptic against gonococcic infections, Dr. Cabot employs one of the silver salts. In order to decide which one of the silver salts is most effective he made a series of observations upon their antiseptic qualities. A one-per-cent. solution of argonin kills gonococci in twenty-four hours; a five-per-cent. solution absolutely prevents growth. Solutions of protargol of corresponding strength give about the same results. On diphtheria bacilli the same effects are produced. No observations were made as to the effect of these solutions on cultures of the gonococci. When cultivated on artificial media the gonococcus is a very weak and delicate organism, so easily affected by unfavorable influences that its destruction constitutes no test of the influence of a remedy on this organism when growing vigorously in human tissues.

Technic of Treatment.—Cases of gonorrhea that come for treatment during the first twenty-four hours can be greatly relieved and the gonococci made to disappear from the discharge without fail in the course of a few days. When the gonococci have penetrated, however, beneath the superficial layer of the mucous cells, it is almost impossible to remove them completely and the case is sure to become more or less chronic. At the patient's first visit, before any treatment is instituted, a specimen of the discharge should be taken for examination. Then the patient should be asked to urinate and after this the urethra should be washed out with warm water. A solution of argonin, 5-10 per cent., should then be injected deep into the urethra by means of a bulb syringe. About six drams of the solution should be employed and it should be retained within the urethra. Gentle kneading of the penis should be employed to bring all parts of the urethral mucous membrane in contact with the solution. As the solution is allowed to escape an applicator with a ten-per-cent. solution of argonin should be used to wipe out the urethra. If this is inserted while the solution is still retained within the urethra no difficulty will be experienced and no pain produced. Cocaine should not be used to deaden the pain as injury of the delicate urethra is thus rendered easier.

Other Treatment.—Citrate of potash should be used plentifully to render the urine bland. The penis should be thoroughly soaked in warm water about three times a day. Where the case presents a copious discharge, this prescription may be given:

℞ Plumbi acetatis.....
Acid. tannic.....
Zinc. sulphat.....
Cupri. sulphat.....aa. grs. ij

This should be prepared in tablet form and the tablet should be dissolved in four ounces of water and used after each urination. When this system of treatment is followed the gonococci have usually disappeared at the end of a week and the discharge ceases in from eight to ten days. Examinations for gonococci are made every two days. The solutions that are employed should be hot, the temperature being not less than 110° F.

The Newer Silver Salts.—In the discussion Dr. Fuller said that the recently-introduced silver salts, cascates and so forth, have proven to be especially unirritating to mucous membranes. There is no doubt that the silver salts are the most efficient agents for the destruction of gonococci. Silver nitrate, however, nearly always proved too irritating. The old abortive treatment by the use of strong solutions of silver nitrate, if it did not succeed in destroying all of the gonococci present, left an extremely favorable soil for the growth of the gonococcus. The inflamed tissues presented the most favorable culture medium and the resistive vitality was very low. Argonin, while quite as efficiently antiseptic as nitrate of silver, is practically non-irritant. If a case of gonorrhea comes for treatment before burrowing of the gonococci has taken place there is a good chance for the abortion of the disease by the use of this agent. Many of the methods of treatment suggested, as, for instance, the irrigation method, seriously disturb the urethra. Of course very few patients will consent to make two visits a day to the doctor. As soon as the discharge becomes but slight, the patient bolts and then relapse ensues and the gonorrhea assumes a chronic condition. Whenever the inflammation extends as far as the bulbous portion of the urethra, all attempts at abortive treatment, or any irritative local treatment, should cease. Abortive treatment to be successful must be begun early.

Success in Abortive Treatment.—Dr. Howard Lilienthal said that the absolutely essential con-

dition of success in the abortive treatment of gonorrhea is to kill all the germs present by the first injections. If any of the gonococci escape the antiseptic, the subsequent course of the gonorrhea is always made worse, as the micro-organisms find a most favorable nidus in the irritated tissues. This was especially true under the old method of the use of nitrate of silver. Argonin does not produce so much irritation, so that the new method of treatment deserves a trial. Some other way of combating gonorrhea than by direct killing of the gonococci is needed. Gonorrhea is recognized generally as a self-limited disease. Some change takes place in the blood and the tissues which makes them an unfavorable breeding-place for gonococci. Perhaps it is not too much to expect that at some time a specific will be found which will produce a corresponding action through the circulation. This specific may prove to be a serum that will kill the germs even though they may be deep in the layers of urethral tissue.

Gonococci and Temperature. — Gonococci grow only in a very limited range of temperature. Whenever the medium in which they are growing is kept at a temperature much above 105° F. they perish. Because of this Dr. Lilienthal hoped some years ago to abort gonorrhea by raising the temperature of the penis above that at which gonococci usually live. By means of coils and even continuous irrigation the temperature of the urethral tissues was raised. The gonorrheal discharge ceased under the treatment, but came back as soon as the temperature was allowed to sink to normal.

The Oleoresins.—Dr. Lilienthal said that the oleoresins—cubebs, copaiba and sandal-wood oil —seem to exert a specific action on the discharge of gonorrhea. The secretion from the inflamed urethra is certainly much less while these drugs are being administered. It is usually said that this diminution in the discharge is due to the fact that the oleoresins make the urine bland. The administration of copious draughts of water suffices to make the urine bland, but does not affect the discharge in the same way as the administration, for instance, of sandal-wood oil. Dr. Lilienthal has seen the discharge stop and then when the sandal-wood oil was discontinued the discharge reasserted itself. It disappeared later, when the sandal-wood oil was resumed, but reappeared as soon as the administration of the drug was stopped. Unfortunately, while the oleoresins limit the amount of the discharge, they do not cause it to stop entirely and so fail of the proper purpose of curing gonorrhea.

The Silver Salts.—Dr. Frederic R. Sturgis said that there is no doubt that the silver salts have a specific action upon gonococci. This gave nitrate of silver its old time popularity. But this special drug is too irritating for most urethras. It must be remembered, however, that the first inch of the urethra is much more sensitive than the deeper parts. Application of twenty-per-cent., thirty-per-cent., and even fifty-per-cent., solutions of nitrate of silver have been made in deeper parts of the urethra without producing any reaction. The recently-introduced silver salts without irritating properties must be the choice in the present-day treatment of gonorrhea. Of these the best seems to be protargol, and after this argonin. These salts should be used in a solution of at least five-per-cent. strength, and a ten-per-cent. solution makes a good average remedy for ordinary practice. Irrigation undoubtedly does as much harm as good. It irritates and inflames the canal and so renders the disease inveterate. There is not much danger in washing infective material back into the bladder, if the urethral canal is well cleaned out. When the patient urinates afterward the lips of the meatus should be held together for a moment so as to secure the natural flushing effect of the dilatation of the canal thus produced. Dr. Sturgis does not use a swab after the injection, but makes applications through the endoscope. These always do good and never harm unless the anterior urethritis is very acute. Then, of course, no endoscope should be employed.

Temperature of Injections. — Dr. Sturgis thinks that the injections should be given at as high a temperature as the patient can stand. This should always be 120° F. and can often be even 140° F. When the doctor can not bear to keep his hand on the syringe the patient may make no complaint of discomfort, but on the contrary may find the warmth rather pleasant. If the discharge is more than forty-eight hours' duration when the patient comes for treatment, there is no prospect of the abortive treatment being successful. Dr. Sturgis has not had cures in less than fourteen days.

In closing the discussion Dr. Cabot said that in the cases in which he had succeeded in successfully aborting gonorrhea have come within twenty-four to thirty-six hours after the first symptoms. The heat of the injection is important and should be as high as can possibly be borne. The strength of argonin solutions may be increased very much without producing irritation. Dr. Cabot has used thirty-per-cent. solutions without producing more unpleasant effects than with ten-per-cent. solutions.

Dr. Brewer said that when the oleoresins are administered injections into the urethra are borne much better than when this medication is neglected.

Ruptured Spleen.—Dr. N. B. Potter reported a case of ruptured spleen which he had seen during the week. The patient, a South American, was first seen on Monday after he had had a chill. His temperature was found to be 103.4° F. On Wednesday there was another rise in temperature and the spleen was found to be very much enlarged. The patient was very anemic, but there was no apprehension as to a fatal termination. During the afternoon of Wednesday serious symptoms developed, signs of internal hemorrhage showed themselves, and before surgical aid could be rendered the patient died. At the autopsy death was found to be due to rupture of the spleen. About half a pint of blood was found in the peritoneal cavity. Cases of spontane-

ous rupture of the spleen are rather rare. Very slight trauma is sometimes sufficient to produce rupture in the acute enlargement of the spleen due to severe malaria. So simple an act as defecation or sitting up in bed can prove the immediate cause of rupture of the spleen.

Was the rupture of the spleen in this patient caused by manipulation during examination of the patient? All of the manipulations were done very gently and the symptoms of the rupture did not begin immediately after the examination, but several hours later. Moreover, the tear in the capsule of the spleen was not on the anterior portion, but was well back beneath the ribs. Besides, the appearance here was that of spontaneous fracture, for there seemed to have been a hemorrhage within the spleen, the pressure of which finally caused a tear in the capsule. Rupture of the spleen occurs usually only in tropical countries and in regions where severe malarial fever abounds, as in certain parts of Italy.

Omental Cyst.—Dr. Brewer reported a case of a child, six years of age, who was operated on for what was thought to be tuberculous peritonitis. The little patient had been under treatment for six or seven weeks in the medical ward and besides moderate fever had considerable abdominal distention. A distinct wave of fluctuation could be elicited and the liver was pressed up beneath the rib margins. Aspiration brought away a fluid slightly tinged with blood, and as the child's condition did not improve operation was decided on. When the child came to the operating-table it was noted that the enlargement caused by the presence of the fluid gave a distinctly fusiform or spindle shape to the patient's trunk. Some infiltration of the right apex had been noted and was considered sufficient to justify the diagnosis of tuberculous peritonitis. On opening the abdomen what was found was a huge cyst within the great omentum, the pedicle of which lay between the stomach and the transverse colon. The cyst-wall was so thin that it ruptured even on very gentle manipulation. The pedicle being ligated the cyst was removed and the patient recovered.

Dr. Gibson said that he had seen the same patient at St. Luke's Hospital where he came demanding an operation. In another patient he has seen the same inexplicable desire for laparotomy. When this individual came first he claimed to be suffering from recurrent appendicitis of which he had had, according to his own story, seven attacks. His appendix was removed and was found to be seven inches in length and quite thin, but seemed perfectly normal. The pathologist reported that it was absolutely normal. Later the same patient turned up at Roosevelt claiming that he was suffering from appendicitis and demanding another operation, later still he was heard of at Bellevue, bent on the same mission. It seems evident, then, that there is a class of cases in which patients morbidly exaggerate their symptoms with the purpose of having operations done for which there is no need.

In discussing the case Dr. Foote said that he had seen one cyst of the great omentum in the autopsy-room at Strasburg. Its nature proved a mystery until Von Recklinghausen himself was consulted, when he suggested a careful examination of the abdomen for hydatid cysts. After a good deal of search two small cysts were found in the lower part of the abdomen. In that case, as in Dr. Brewer's, the cyst-wall was very thin and almost transparent.

Dr. Coley said that he had once encountered omental cysts in a hernial sac. Several of them were drawn down with the omentum and carefully tied off.

Laparotomy Mania.—Dr. Foote reported the case of a young man who came to the hospital suffering from an obscure and, as he claimed, painful condition in the abdomen. His subjective symptoms pointed to some pathological condition in the right iliac fossa. Examination of his abdomen showed the presence of the scars of four laparotomy incisions. He claimed that he had been operated upon first in Russia and that something had been removed from his abdomen, although just what it was it was hard to make out. He had been three times operated upon in this country and it is evident that he has been making the rounds of the hospitals for the purpose of having abdominal operations done for imaginary or feigned ailments.

NEW YORK ACADEMY OF MEDICINE—SECTION ON MEDICINE.

Stated Meeting, Held December 18, 1900.

John H. Huddleston, M.D., Chairman.

Treatment of Acute and Chronic Alcoholism.—The first paper was by Dr. A. R. Braunlich, Interne at Bellevue Hospital, on Acute Alcoholism at Bellevue. Dr. Braunlich said that the cases of acute alcoholism which come for treatment may be divided into three classes. First, acute alcoholic intoxication; second, delirium tremens; third, alcoholic mania. Occasionally other complications of alcoholism are seen in the alcoholic ward—as melancholia, alcoholic neuritis, alcoholic epilepsy and epileptic mania, brought on by overindulgence in spirituous liquors. These last conditions are rare, however, for, as they are either chronic or need treatment especially for their mental trouble, they are usually transferred to other departments. The most frequent form of alcoholism is an emotional boisterous stage. This is treated routinely by a dose of thirty grains of potassium bromide and fifteen grains of chloral hydrate. These remedies are repeated in an hour if the patient's symptoms continue. The patient is persuaded to get to bed as soon as possible and after a few days of rest can usually be discharged without more ado.

Dead Drunks.—A second important class of cases are the dead drunks. For these a stomach-tube is used immediately after their entrance

and their stomachs thoroughly cleared of any alcohol that may be present. External heat is then applied and the patients are rolled in blankets. One-thirtieth of a grain of strychnine is administered hypodermically and one to two minims of the fluid extract of digitalis. There often exists in these cases an acute gastritis with very persistent emesis, which increases the prostration and further disturbs the patient. For this morphine is given in doses of one-fiftieth of a grain, subcutaneously, every fifteen minutes to one-half hour, until the patient is able to retain fluid. Fluid is first given in very small quantities, not more than a dram of milk or water at a time. Even this is not repeated frequently, until retention is assured.

Delirium Tremens.—When symptoms of delirium are manifest in chronic alcoholic patients, the sudden withdrawal of alcohol has been found to be dangerous in certain cases. If symptoms of cardiac failure assert themselves, a little alcohol must be allowed as a stimulant to the circulation. Other circulatory stimulants should be freely employed. Of these aromatic spirits of ammonia and tincture of digitalis have been found most effective. It must not be forgotten by the advocates of the sudden and complete withdrawal of liquors that these remedies contain a certain amount of alcohol and that this is one good reason for the benefit they do. Strychnine is given hypodermically in doses of one-sixtieth to one-twentieth of a grain, according to the necessity for stimulation. Atropine is given in doses of one-one-hundred-and-fiftieth to one-fiftieth of a grain. Where there is much excitement sodium bromide is given in doses of thirty grains to one dram, one-eighth of a grain of morphine is given hypodermically and one-one-hundredth of a grain of hyoscine. A wet pack proves very soothing and its use will often obviate the necessity for the administration of strong hypnotic drugs. After the stage of excitement is past, forced feeding is the treatment especially indicated.

Forced Feeding in Alcoholism.—After an attack of delirium tremens, the patient must be tempted to take as much food as possible for at least a week or ten days. One of the members of the visiting staff at Bellevue uses so many eggs for his alcoholic patients that there has been a protest from the commissary department of the hospital because of the expensiveness of this article of diet at certain times. At least six to eight eggs a day should be used by convalescent alcoholics. They are the most easily digested concentrated food that can be used. After an attack of delirium tremens it must be remembered that patients are very prone to suffer from almost unquenchable thirst. Water should be given very freely then and nurses should be instructed to see that at least every hour some water is offered to the patient, or a fresh supply placed beside him. The aqua ammonii acetatis may be used freely and will be found to be very refreshing and stimulating.

Alcoholic Mania.—For this condition the best drugs to produce quiet are morphine and hyoscine. Patients need to be carefully restrained and usually require the services of a special attendant. Where the mania lasts for some time patients are not kept in the ordinary alcoholic ward, but are transferred to the insane pavilion. Alcoholic neuritis runs so chronic a course that very few cases are retained in the alcoholic ward. Epileptic mania due to alcoholism is transferred to the insane wards. All of these cases of mental aberation due to alcoholism should be closely watched as regards the development of organic disease and especially pneumonia. It must also be borne in mind that pneumonia in alcoholic patients often causes a delirium that may for a time simulate maniacal excitement and lead to a mistake in diagnosis.

Treatment After Acute Attack.—For the anorexia which so often follows an acute attack of alcoholism, a prescription containing ten minims each of capsicum, nux vomica and ginger is often of great service. For this state of anorexia and general relaxation, exercise in the open air has been tried, but it was found that where patients walked much their convalescence was slower. Rest is an important element in the treatment of the exhaustion which follows acute alcoholism. If the alcoholic gastritis is severe capsicum is contraindicated, because it is so irritant. In a number of cases of wet brain, lumbar puncture was tried. In some of the cases improvement followed, but there seemed to be very little if any direct effect. At the beginning of excitement such as may come on sometime after an excess and its effects have passed off, thirty grains of bromide and fifteen grains of chloral repeated if necessary will prove a useful remedy. In general forced feeding and sufficient stimulation are the important element in the treatment of alcoholic cases, after acute symptoms have passed off.

Classification of Chronic Alcoholism.—Dr. T. D. Crothers of Hartford, Connecticut, said that all inebriates may be grouped under three heads: (1) The paroxysmal, (2) the delusional, and (3) the senile, or demented. Under inebriates are included all who take alcohol to excess. Alcoholism means simply a poisoning of the system. Inebriety is a pathological condition having a definite cause and recognizable symptoms and the taking of alcohol to excess is usually only one of its symptoms. Paroxysmal inebriates are those who take alcohol to excess periodically and then abstain sometimes for long intervals. The intervals are often regular, but may be irregular. There is often a precise uniformity in the return of the impulse to take stimulants, which it is difficult to understand. The attacks are sudden, and there seems to be a distinct neurotic cycle in the organism. A man of distinction, who suffers from periodical attacks of inebriety, has his impulse to take stimulants return every ninety-one days and some hours. At that time no consideration is able to in-

hibit the impulse. It is a true insane idea, an imperative emotion. When such attacks recur, they often come without premonitions. After some experience, however, the patient is able to recognize that an attack is coming. If he should be prevented from procuring stimulants an almost maniacal state develops. Another intelligent patient has his impulse to take alcohol return every ten months. He has put himself under a doctor's care several times, but has not succeeded in preventing a return of the morbid impulse. Many patients conscious of these recurring impulses go to a hotel in a distant city for some days, drink to their satisfaction in their rooms and then return to business. Others go to sanatoria and reformatories in the hope to put off the temptation.

Causes of Alcoholic Impulse.—These drink-storms return at such irregular intervals in most cases that it is often hard to determine their causes. Usually a condition of exhaustion has supervened in the patient just before the impulse takes possession of him. Often the attack is preceded by a period of overwork, nervous strain, mental worry. Often it is accompanied by unusual excitement and mental disturbance. Such patients, if interfered with, have moments of destructiveness and are prone to use abusive language, though at other times they may be utterly unaccustomed to it. This condition represents the true dipsomania. A thirst for spirits seldom grows into this maniacal impulse. The dipsomaniac may have more or less repugnance to alcohol between his attacks. The neurotic basis of the affection is thus made clearer and the necessity for its treatment as a nervous and mental condition made more emphatic.

Delusional Inebriates.—The first symptom of this condition is often an increased confidence in the part of the patient in his power to overcome the drink thirst. He knows that he has tendencies to take more spirituous liquor than is good for him, but feels sure that whenever he wishes he can break up the habit. This delusional condition extends after a time also to other subject-matters. The patient is sure that he is able to accomplish other things quite beyond his power. When on any special occasion he fails to overcome his habit he offers the most childish explanations and considers them amply sufficient. Some of the reasons given are the typical reasons of insane minds. At times in these cases, paresis develops and the picture is one of delusions of grandeur. As a rule such patients develop a boundless confidence in remedies of all kinds and especially drink remedies. The more secrecy is attached to a method of treatment the surer are they of its efficiency. These constitute most of the class of people who set themselves up as examples of wonderful cures. Their relapse into their old habits is only a matter of time. After a while such patients develop other delusions, especially those of persecution. They insist that friends are forcing them to suicide. Electricity appeals strongly to their imagination and they are frequently convinced that friends are using electrical contrivances on them for the purpose of torturing them. Such patients are prone to intense jealousy. As the result of these delusions of persecution they may themselves in turn become persecutors and commit violent acts.

Senile or Dementic Alcoholics.—These are patients usually of feeble mentality who drink almost without purpose. Where alcohol is not easily obtained they do not take it. They do not drink while in the country, but drink almost continually in the city. Very often these patients are degenerates from birth and the wear and tear of life would seem to have used up all their will power. Sometimes this senile or dementic alcoholism develops as the result of brain injuries or shocks. This traumatic form is rather easily recognized. At times dementic alcoholism is the result of exhausting disease. Not infrequently it is the terminal stage of the paroxysmal form of inebriety. Sometimes such patients go into the saloon business for no other purpose than to be in a position to take stimulants at all times.

Treatment.—The first and most important element in the treatment of inebriety is thorough control of the patient under circumstances that make the getting of alcohol an impossibility. For this to be successful a change of surroundings and external conditions with a home among strangers is absolutely necessary for severe cases. An asylum at a long distance from his home is the best beginning of the treatment. If the patient is in the midst of a paroxysmal drink-storm when he comes under treatment, the question of the withdrawal of spirits is of importance. Notwithstanding the tradition in the matter, the sudden withdrawal of spirits will not cause delirium if baths and salines are used freely. The taste for alcohol may be overcome by giving two ounces of quassia every two hours, until a feeling of disgust for alcoholic drinks is produced. Other bitter tonics, notably cinchona, produce this same effect. An adjuvant remedy in these cases is apomorphine, which may be used in doses of one-sixtieth of a grain, until nausea is produced and this will limit the craving for alcohol. The stimulant effect of alcohol may be replaced by nux vomica, given in good quantities. A quarter-of-a-grain pill may be given every two hours.

Poisoning and Starvation.—After the effects of an attack of acute alcoholism have passed off two serious conditions usually remain. One is a poisoned condition of the system due to the presence of alcohol and its produces in the tissues—the other is starvation due to the anorexia. The poison should be eliminated from the system as rapidly as possible. For this hot-air baths, or, if these depress, electric-light baths should be employed. Electric-light baths are given by placing the patient for some time in a flood of electric light. It has been shown that perspiration occurs more freely, even at the same temperature of the room, when the skin is exposed

to strong light. A rapid and intense elimination of poisonous products occurs through the skin. After this free sweat a feeling of exhilaration takes the place of the sense of depression, the patient becomes more restful and sleeps well.

Latent Organic Disease.—Alcoholic excesses often lead to the concealment of organic disease until these affections have developed to an alarming stage. This is especially true of tuberculosis. The effect of alcohol and of the toxin of tuberculosis are not unlike. Members of the same family that suffer from the toxins of alcohol and from the toxins of tuberculosis may exhibit similar symptoms. This accounts for the insidiousness with which the tuberculosis may develop.

Narcotics.—Narcotics must be used with caution and so far as possible only the milder drugs of this type employed. Lactucarium, lupulin and valerian are important drugs in this respect and will produce much more quieting effects than is usually thought. Bromide of soda is a useful remedy and is preferable to the bromide of potash, but should be given in sufficiently large doses. Where marked restlessness exists fifty to one hundred grains of the drug should be administered at a dose. If syphilis exists with the alcoholism, mercury and the iodides must, of course, be given. They will then be found to control many of the symptoms which were supposed to be due to the alcoholism and will save the use of strong narcotics.

General Treatment.—Arsenic is a very good remedy for its general tonic effect. Phosphate of soda should be given continuously for some time after an acute attack of alcoholism. It acts as an hepatic stimulant and its eliminative action makes it very valuable. The other indications are for rest, food and frequent warm baths. These baths are particularly useful because of their eliminative action. The mental treatment of alcoholics is important. The influence of suggestion and good example must not be lost sight of and the patient must be provided with constant mental diversion so as to keep from brooding over his condition. There is no specific treatment for alcoholism. Sometimes the drink craze proves to be self-limited. The last remedy that has been used is then thought to account for the change that has taken place. The reason for the alteration in the patient's character seems to be some change in the brain material. The hope is that a change like this can be led up to by institution treatment.

Hypnosis for Alcoholism.—Dr. J. D. Quackenboss said that hypnotism is an efficient remedy in the treatment of alcoholism. It has not thus far been employed to the extent that its success justifies. Hypnosis reveals the fact that there is in human nature a dual personality. Each self has a distinct consciousness. The primary self is employed with the ordinary business of life. The secondary self is concerned with the automatic actions of life. It apprehends intuitively and does many things that the primary self is not able to comprehend. One personality does not shade into the other. They are essentially distinct, although they may influence one another for better or for worse. Hypnosis brings out the subliminal or submerged self. The influence of this personality can be employed to overcome the want of energy in the primary self. Dipsomania yields readily to hypnotic suggestion and in these cases hypnotism is as a rule easy of employment. During a state of intoxication hypnotism can not be employed. Just before a drink-storm, however, hypnotic suggestion may prove most effective. Most observers are agreed that there is an intimate relation between the use of tobacco and alcohol. When tobacco is used to excess the alcohol habit is usually a concomitant, and when drink-storms come on they have often been preceded by a period of greater use and abuse of tobacco than usual. The periodicity of dipsomanic attacks is quite marked. The longest period that Dr. Quackenboss has seen was three years. Often it will be found that spells of crankiness, lowered inhibition and lack of resistance to irritation, immediately precede the outburst of acute dipsomania.

Hypnotic Technic.—Once a patient has been brought under the influence of hypnotism, carefully thought out suggestions should be impressed upon him. He should be told, for instance, that alcohol will disgust him, that he will not be able to bring a glass of liquor to his lips, that the use of it with food will cause the food to disagree with him. Then the mental picture should be impressed upon him of the effects of alcohol. The meretricious attractions of the barroom should be set off by picturing to him, while in the hypnotic state, the delights of a chaste home-life. Apprehension of the results of alcoholism should be aroused and at the same time promises given of glorious success in his effort to overcome the habit. In giving these suggestions sincerity is absolutely necessary. They must be in the nature of an inspiration. The words must not be mere lip-work, nor a rote lesson. There must be a reciprocal transfer of personality. The hypnotic subject recognizes in his trance state at once any disingenuousness, or lack of candor that may be present. The consent of the patient must, of course, be obtained otherwise he will not respond to suggestion. It is not enough for him to come to receive hypnotic suggestion for the cure of his drink habit, merely because friends have insisted on it. He must have a sincere desire himself. While in the hypnotic state this desire may, however, be thoroughly awakened in a vascillating spirit. This can be done by pointing out the dangers there are in alcoholism. The treatment must not be abandoned too soon and it must be remembered that it does not guarantee against relapse. No remedy nor set of remedies that we have will guarantee against relapse in any disease. As in rheumatism, tonsillitis, and diphtheria, one attack of dipsomania predisposes to others. Even though the patient is cured for the time the dis-

case may return. In addition to hypnosis other therapeutic methods should be employed at the same time. The patient should be thoroughly stimulated by means of strychnine, or coca, if that is deemed necessary. In acute excitement and restlessness bromide of potash and chloral should be used freely. In the milder forms of restlessness the valerianates should be employed. In the last two years, Dr. Quackenboss has had under treatment forty inebriates. In about fifty per cent. of these cases that are still under observation there has been no relapse. The longest cured case passed from treatment about a year ago. Thirty-three per cent. of the patients have been lost sight of; seventeen per cent. are known to have relapsed; about one-half of these latter cases were known to be hopeless from the beginning. Where degeneracy exists and alcoholic deterioration of the brain has already taken place, hypnotism does not produce its usual effect and relapses are not infrequent.

In closing the discussion Dr. Crothers said that suggestion with or without hypnosis is very useful in the treatment of alcoholism. The damaged brains of alcoholic patients do not, however, hold impressions long. Impressions are only superficial. The pietist and the moralist have shown us how transient are the effects of suggestion, though they must be tried even unto ninety-nine times and occasionally they do produce lasting good effects. In answer to a question, Dr. Crothers said that after fifteen years about thirty-three per cent. of patients that have been under his care are without relapse. Some of the patients have been more than twenty years without taking liquor. In one case after eighteen years of abstinence the drink habit was reestablished. It is very difficult to give any prognosis in individual cases, or to calculate the average of cures.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held December 4, 1900.

The President, Frederick Peterson, M.D., in the Chair.

Terminal Condition in Diplegia.—Dr. William M. Leszynsky presented a man, twenty-one years of age, in whom the chief feature of interest was a trembling of the hands, which had existed as long as he could remember. Nothing was known of his early history except that he had always been nervous. His mother had died of cancer of the uterus. The trembling had always been more marked on the left side, and his condition was apparently growing steadily worse. On careful examination no disturbance of sensibility could be detected. There was excellent muscular development on the left side and a spinal curvature, probably arising from the use of one side more than the other. There was no signs of atrophy. There was some asymmetry of the cranium. There was no disturbance of vision, but concentric contraction of the visual field. There was no nystagmus, and the pupils and fundi were normal. There was a positive tremor when at rest, and a more active tremor on motion. He holds the left arm in extension, but close scrutiny shows that all of the rigidity is in the extensors. The elbow-jerk was elicited only on the right side. Both knee-jerks were exaggerated. Ankle clonus had been demonstrated on both sides, although much more marked on the left. Dr. Leszynsky said that this man had probably recovered from a paralysis that he had had at one time, and was now suffering from a terminal condition of an infantile palsy. Undoubtedly there was a good deal of functional disturbance added to the organic trouble.

Dr. M. Allen Starr thought the case was an athetosis on the left side, and that probably the same lesion, to a minor degree, was present on the opposite side. It was apparently a post-diplegic condition.

Dr. E. D. Fisher looked upon the case as one of cerebral diplegia most marked on the left side, and with the athetoid movements often seen in such cases. This extreme muscular development seemed to him not at all uncommon in this class of cases. He would like to know concerning the electrical reactions.

Dr. B. Sachs said that there could be no doubt that the left side was the center of disturbance, and it was also probable that a part of the tremor was functional. The condition of the muscles in the scapular region seemed to him fully accounted for by the spinal curvature present.

Dr. F. Peterson agreed with the diagnosis of postparalytic athetoid form of movement. Where the paralysis was small he thought these finer movements were more apt to be present.

Dr. Leszynsky had not yet tested the electrical reactions. It seemed to him that this man could be benefited if properly trained. Hypnotism had been suggested, and it seemed to him worthy of trial. The method used for ataxics would probably prove beneficial; it had just been commenced.

Two Cases of Spinal Tumor, Operation and Removal.—Dr. M. Allen Starr said that five years ago he had been able to collect 145 cases of spinal tumor, in twenty-two of which operation had been undertaken. In the cases forming the subject of the present paper the symptom pain had been very prominent, and this together with the symptoms of pressure on the cord had allowed of the diagnosis being made.

Case I.—Mrs. E. W., thirty-five years of age, had been in good health previous to March, 1899, at which time she had begun to suffer at night from paroxysms of pain near the heart. They were not brought on by exertion, but were much increased by touching a region to the left of the nipple. From September, 1899, to May, 1900, she had been treated by many physicians for angina pectoris, hysteria and other disorders. Nitroglycerin had always intensified the pain.

On May 10th Dr. Theodore Janeway had examined her and found her in an extremely nervous condition and suffering from constant pain. The left knee-jerk was exaggerated. Over the left side of the dorsal spine was extreme sensitiveness from the first to the eighth dorsal spine, and over the corresponding intercostal nerves at the angles of the ribs. There was no affection of the arms and the internal organs were normal. When examined by Dr. Starr on October 20th she was suffering much from pain at the level of the fifth and sixth intercostal nerves, much more marked on the left side. There was very marked tenderness over the dorsal region from the first to the seventh dorsal spine. A condition of partial anesthesia was found on the trunk and total anesthesia in the legs. Her legs were quite powerless, but there was no atrophy of the muscles. Ankle clonus was present on both sides, and both limbs were cold, blue and edematous. She had recently been unable to control the sphincters. Dr. Janeway had made a diagnosis of tumor of the spinal cord at the fifth dorsal segment. On October 22d she had been operated upon by Dr. McCosh at the Presbyterian Hospital. On dividing the dura an extremely edematous state of the wall was observed, with one white plaque lying upon it. The cord was smaller and whiter than normal, and was not pulsating. No tumor was found. Three days later the wound was enlarged upward and the dura found to pulsate freely at the upper level, but not lower down. A tumor, 1⅛ inches in length, lay upon the cord. It was oval, had a distinct capsule, and was removed *en masse* without difficulty. Subsequent examination showed it to be a fibroma. The cord had been reduced to about one-half of its diameter beneath the tumor. No attempt was made by nature to heal the first operation wound, and in spite of great care an extensive bed-sore developed over the hip. In the second week after operation the constricted feeling became less marked. The operation wound healed very slowly. In the fourth week after the operation the patient had constant fever, probably because of the extensive bed-sores. The spinal incision healed about this time, but she died a few days later. The autopsy showed a softened condition of the cord opposite the exit of the second dorsal nerve from the dura, and the fifth and fourth dorsal nerves could be traced into this area. Owing to the rudimentary condition of the spine of the third vertebra an error of one vertebra had been made in the count at the time of operation. The case seemed to emphasize the fact that there should be no delay in operating for spinal tumor after the diagnosis had been reached. In this case the delay had arisen from an effort to try the effect of antisyphilitic treatment, the husband being known to be syphilitic. Bed-sores had developed before the operation, had continued to extend in spite of it, and had eventually caused death from sepsis. Gumma of the spinal cord is quite rare, only twenty-six such cases having been found in a series of 400 cases. The tumor had been found about two inches higher than had been anticipated. Reed's table had been used as a guide at the first operation, but according to Bruns the operation should be done two segments above the upper limit of pain. This advice was nearer the truth in the present case. The level of the pain was about eight inches lower than the level of the tumor; hence, in operating for spinal tumor the level of the cord should be exposed at least four inches higher than the level of the spinal nerve in which pain is found.

Case II.—Mrs. K., forty-six years of age, had been in good health until May, 1900, when after a slight injury she had been delivered of a dead child. Soon afterward she had begun to suffer pain over the left hip, and this pain had extended down to the left knee. It had caused insomnia and progressive loss of health. In September she had noted numbness of the left foot. On October 16th, on admission to the Presbyterian Hospital, she was pale and feeble, and seemed to be suffering from paroxysms of pain over the left trochanter and that side of the sacrum There was drop-foot due to paralysis of the peronei and anterior tibial muscles. The bladder required catheterization, and the rectum had to be emptied by enema. There was an area of anesthesia down the back of the left thigh and leg, and a smaller area was found on the right side. Under mixed treatment the paralysis extended and the pain became more severe. An area of tenderness to pressure was found over the second, third and fourth lumbar vertebræ, and pressure here aggravated the pain in the hip. It seemed probable from these facts that there was a tumor pressing on the cauda equina, and extending as high as the level of the exit of the second lumbar nerve. The functions of the sacral nerves and last lumbar nerve were evidently affected on the left side. A diagnosis of a cauda lesion was reached because of the level of the pain. On November 15th Dr. McCosh removed the spines and arches of the second, third and fourth lumbar vertebræ. Dissection showed a tumor involving both the soft and hard tissues of this region. The spines and arches had been eroded by the tumor, which subsequently proved to be an endothelioma. This tumor had invaded the spinal canal and produced pressure on the dura. The patient was in a critical condition for two days after operation, but since then had improved rapidly and had had no pain since the operation. A considerable degree of atrophy had developed in both peronei. The wound had healed perfectly and there was no evidence of recurrence. It was reasonable to hope for recovery unless there should be speedy recurrence. Out of 145 cases of spinal tumor that he had collected, the history had been fairly clear in 122. Of seventy-six cases an operation should have been feasible, and according to the pathological report in 75 per cent. the tumors could have been removed.

Dr. A. J. McCosh said that he had found spinal surgery much more satisfactory than brain surgery; certainly the localization of the lesions had been more satisfactory. It was difficult to say, however, that a lesion is situated at any one segment of the spinal cord, but as a portion of the cord equal to three or four vertebræ must be exposed a slight error in localization is not of great importance. He had had recently a case presenting symptoms almost exactly like those of the first case reported in the paper. The line of anesthesia had been almost the same, but there had been no paralysis of the arms. The autopsy showed a crushing injury of the cord between the fourth and sixth cervical vertebræ. The ordinary rules laid down had indicated a lesion much lower down, and he had in this way been misled at the operation. He had not found laminectomy a very serious operation as a rule, most of the patients having exhibited comparatively little shock; hence, one should not hesitate in advising the operation when the diagnosis was sufficiently clear. He agreed thoroughly with what Dr. Starr had said about the inadvisability of delaying the operation for weeks in order to give antisyphilitic treatment a trial. He had met with a number of cases in which he believed the fatal result was attributable to such delay. When bed-sores were already present the case was practically hopeless, the patient almost invariably dying from sepsis. It was well to remember that tumors of the cord are usually found higher up than the estimated level. By beginning above and working downward, it seemed to him that the healing process would be favored. He was not of the opinion that there was any good ground for believing that the operation of laminectomy so weakens the spine as to lead to disability. Mention was made of one of his cases in which a man was engaged at an occupation requiring the frequent lifting of heavy weights, yet he had felt no inconvenience as a result of the operation upon his spinal column.

Dr. Pearce Bailey reported the case of a man, forty-one years of age, who had been treated for some time previously for a variety of troubles. When seen in May he had stated that about fifteen months previously he had begun to have intense pain on the inner side of the left thigh. There had been an interval of a few months in which this pain had almost subsided. There was slight atrophy in the left leg; the left knee-jerk was absent; there was very slight anesthesia. The case seemed to be one of tumor of the cauda equina. Dr. McCosh had operated upon him on May 22d. He had removed the last dorsal and the first and second lumbar vertebræ, and had exposed what had looked at first like a blood-clot, but microscopical examination had proved this to be a round-celled sarcoma. Although it was probable that all of this sarcoma had not been removed, the man had done extremely well all these months, was free from pain and had resumed his occupation.

Dr Sachs coincided with those who had advised against delaying in these cases in order to try specific treatment. He was thoroughly in favor of operating just as soon as the diagnosis had been established with reasonable clearness. It was a great mistake in his opinion to look upon operation as a last resort. Gumma of the cord was quite rare, and even in these cases very little had been accomplished by the administration of the iodides; hence, such treatment might very well be neglected. In one of his cases in which the operation had been done quite early the man had been restored promptly to health. In another case he had not been allowed to operate early, and the recovery had been far from satisfactory. It seemed to him that a little too much importance was attached to the mere matter of localization; the important question was in regard to the nature of the morbid process and whether or not a tumor is present. In Pott's disease the sensory disturbances were sometimes as marked as where there was a tumor of the cord. Pain was the important symptom, but this was applicable more particularly to dorsal rather than to ventral tumors. He was not prepared to speak regarding the relative frequency of these two forms of tumor. He was of the opinion that a very extensive laminectomy could be done without causing notable disability or deformity. Early operation, he felt sure, would make spinal surgery much more satisfactory than brain surgery.

Dr. Theodore Janeway said that he regretted very much that in his case the diagnosis of spinal tumor had not been made sooner. There had been pain a year previously, but the pain had disappeared for a considerable time, and when he had first seen her she had been so extremely nervous that the question of hysteria had been seriously considered at first. The case had progressed very rapidly during the part of the summer in which he had not seen her.

Tuberculous Meningitis at the Babies' Hospital.—Dr. C. A. Herter read a paper with this title. There were 24 cases of tuberculous meningitis, and in 15 of these there were autopsies. In these 15 cases, 6 were at the age of eight months; 7 were one year old or under. In 9 cases of tuberculous meningitis without autopsy 6 were five months old. These figures showed that tuberculous meningitis was not so rare in the first year of life as had been supposed by some writers. Nineteen of the cases had run their course in less than one month. The fontanelle had been markedly distended in 7 of the 24 cases, and in 3 there had been a marked excess of fluid found at autopsy. In one case the fontanelle had been depressed—the patient had been sick for four or five months. In six cases there had been a delay in the closure of the fontanelle. Vomiting had been noted in 19 of the 24 cases, and had been the first symptom in 14 cases. In five in which there was vomiting the autopsy showed nothing different from the cases that had presented vomiting. In 11 cases

there had been marked constipation. In cases coming to autopsy there had also been tuberculous lesions in the intestine. In several of the cases there were tuberculous ulcers of the colon and yet constipation instead of diarrhea had been present. The pupils were unequal in 12 of the 24 cases, and dilated in the others. The pupils were contracted in only two cases. Nystagmus was observed in 4 cases, and strabismus in 10 cases. In the cases showing strabismus there were marked lesions at the base and in the interpeduncular space. There were general convulsions in 50 per cent. There was no case which did not present either rigidity or convulsions. In cases without meningitis, but with tubercles in the brain, convulsions were not so common. Paralysis was noted in 10 of the cases of tuberculous meningitis, and was monoplegic in a number. The variability of these palsies was a rather notable feature. In the cases without meningitis, but with tubercles in the brain, no palsies or paralyses were noted. The *tache cérébrale* was noted in 7 cases, and flushing of the face in 10 cases. All the cases of tuberculous meningitis with autopsy had presented stupor or coma, or more or less irregularity of respiration, while these had not been observed in any of the cases with tubercles, but without meningitis. Hyperesthesia had been noted in only one case, and in only one had there been a well-developed cephalic cry. Retraction of the abdomen had been noted to a greater or less degree in 15 of the cases of tuberculous meningitis, but not at all in the other cases. The fever had not been high in the uncomplicated cases, and the pulse had shown nothing distinctive. In the cases without meningitis marked opisthotonos and convulsions had been the rule, and early vomiting had been much less frequent than where meningitis was present. Only two or three of the cases had presented solitary tubercles. In all of the autopsy cases the cerebral tuberculosis had been clearly secondary. The intestine was the seat of tuberculous lesions in 11 of the 12 cases in which the intestine was examined. The knee-jerks were increased in a large proportion of cases, and absent in only two. An interesting feature was that at times the knee-jerks would be alternately exaggerated and absent.

Dr. Leszynsky said that he had made some observations in children under three years with regard to the knee-jerk, and had noted that in the early stages the knee-jerks had seemed to be absent, but as soon as the pressure symptoms appeared the knee-jerks became exaggerated and remained so until death.

Dr. Sachs said that the diagnosis of tuberculous meningitis was usually delayed by the general practitioner because he overlooked, as a rule, the cranial nerve symptoms so commonly found quite early in these cases, and waited for some of the more common and typical symptoms. He would like to know whether examination of the fundus and lumbar puncture had been of any diagnostic aid.

Dr. Herter replied that lumbar puncture had been practised in a few instances, and in two or three tubercle bacilli had been found. The examination of the fundus had been undertaken in so few cases that no deductions could be made. None of the cases diagnosticated as tuberculous meningitis had recovered.

Dr. Sachs said that in a series of cases of sporadic meningitis lumbar puncture had been made, and the diplococcus had been found in almost every instance. He had been surprised also at the large number of recoveries in these cases of sporadic meningitis in which the diplococcus had been found. Their clinical course had been greatly at variance with the older descriptions of cerebrospinal meningitis. The onset had been very violent, the fever lasting often a week or more, and then ultimate recovery was rapid.

Dr. Herter said that in the cases he had seen there had been a much more violent onset than in tuberculous meningitis.

ORIGINAL ARTICLES.

A HAIR-CAST OF THE STOMACH; ITS SUCCESSFUL REMOVAL BY LAPAROTOMY.*

BY NATHAN JACOBSON, M.D.,

OF SYRACUSE, N. Y.;

PROFESSOR OF CLINICAL SURGERY IN THE SYRACUSE UNIVERSITY; SURGEON TO ST. JOSEPH'S HOSPITAL.

I DESIRE to present for your consideration a case, which, while not unique, is sufficiently rare as probably not to have had its like observed by many present.

Ella M., residing in Oswego, N. Y., aged eleven years, was referred to me in April, 1900, by her physician, Dr. C. A. Sheridan of that city. Both of her parents are living. A maternal grandmother died of consumption. The child had had scarlatina, whooping-cough, and measles. The latter, her last illness, occurred about two years prior to my examination. For fully six months before that sickness, however, she showed evidence of gastric disturbance. She vomited a good deal of frothy mucus, but never at that time any food or blood. The odor of food frequently provoked emesis.

In April, 1899, a swelling was noticed in her abdomen, which at first was said to have been cucumber-shaped. The following summer she began to suffer from colicky pains. These were frequently relieved by friction or after the administration of medicine. She suffered particularly from pain at night, her father being compelled to hold her in his arms. Most of the pain was located to the left of the umbilicus. Her bowels had been constipated for the past year, and moved only with the aid of cathartics. Food disturbed her so that she was compelled to live largely on milk. Upon this diet she gained some in strength and weight. In appearance, however, she seemed scarcely larger than a seven-year-old child. She felt well enough to attend school. She was quite nervous.

Physical examinations showed the presence of a hard, slightly-nodular tumor, quite movable, the lower border being on a line with the umbilicus. The upper extremity could not be defined as the mass reached well up under the ribs on the left side. Internally it arched upward and became conical. Its lower border being rounded and its upper notched, it presented a kidney-shaped appearance. Its long diameter was about six inches. There was quite an area of tympanitic resonance between the tumor and the liver. The urine was examined and found to be straw colored, clear, specific gravity 1022, sharply acid. It contained neither albumin nor sugar; phosphates were normal: microscopically, uric acid and some squamous epithelium were found. She was sent to St. Joseph's Hospital for more careful study. On April 20th a blood-examination was made by Dr. Kieffer. The following was his report: "Count of red blood-corpuscles, 4,880,000 to the c.mm.; leucocytes, 10,300 to the c.mm.; estimation of hemogoblin, 86 per cent.; color index .9. Stained specimen shows decided loss of hemoglobin in all the red blood-corpuscles. These are all of uniform size and shape. The leucocytes are mostly polynuclear. No nucleated reds present."

Under date of May 17th I have summarized in my note-book the condition of the child after her admission into the hospital. The urine had been frequently analyzed during the intervening four weeks, and each time found to be normal. Occasionally her temperature had reached 99° F. and rarely a fraction above, but as a rule it remained normal. The bowels were kept free by administering salines. She had suffered but little from colic, and what pain she had was usually at night. The movements of the bowels were very copious. This was particularly true of the first days of her stay at the hospital. She had not vomited at all during the entire month. She proved to be an exceedingly bright child. There was no apparent change in the shape or position of the mass. Other members of the hospital staff, as well as myself, repeatedly examined her, but we were unable to agree upon a diagnosis, and finally prevailed upon her parents to consent to a laparotomy.

This was performed on the morning of May 17th, 1900. Drs. Elsner, Miller, Larkin, Flaherty, Broad, and Elliot were present. Drs. Heiman and Shipman assisted me. A median incision was made above the umbilicus. Upon opening the abdomen the kidney-shaped mass was found to be within the stomach. A tube was thereupon introduced, and through it this viscus thoroughly irrigated. An incision was carried through the anterior wall of the stomach, parallel with the greater curvature, about three inches in length, the stomach having been previously walled off from the rest of the abdomen by gauze sponges. I was able to force out the conical point and then the rest of the tumor. It proved to be black in color and made up of a mass of hair. Apparently no leakage of stomach-contents occurred. I closed the stomach incision by first suturing its mucous membrane with continued suture, then by interrupted suture the muscular coat, and, finally, with a double tier of interrupted sutures the serous coat. Catgut was the suture material used throughout. The abdomen was flushed with

*Read at the ninety-fifth annual meeting of the Medical Society of the State of New York, held at Albany, January 30, 1901.

salt water, carefully mopped out, and the abdominal incision closed. The child bore the operation well.

After she had recovered from the anesthetic she admitted that from the earliest years of her life she had been in the habit of biting off the ends of her hair which was always worn long enough to be brought to her mouth. At first she thinks she did it simply because she was nervous. But later she rather liked the tickling sensation produced by the hair in its transit to the stomach.

I am in receipt of a letter from her physician, Dr. Sheridan, dated January 24, 1901, namely, seven months after she left the hospital, in which he writes that the little patient "never had any return of gastric trouble; no pain nor vomiting; and in fact has enjoyed the very best of health. She is as fat and rosy a little girl as you would wish to see; has gained 18 pounds in weight, and is 2½ inches taller."

I present to you the hair-tumor removed from our little patient's stomach. It will be observed that in its contour it presents a perfect cast of

Fig. 1. Hair cast removed from human stomach. Exterior; full size.

She was put upon rectal nutrient enemata for the first week. After this, liquids were administered. During the third week she received first soft and ultimately solid food. Her temperature never reached 100° F. after the operation, and on the third day the pulse, which had ranged above 120, fell to 80, and remained between 80 and 92 until she was well. The abdominal wound healed by first intention. Before she left the hospital we had her hair closely cut.

this organ while in a state of contraction. It is interesting to note that the pyloric prolongation meets the cardiac portion nearly at a right angle, and scarcely can be said to describe a curve. The conical end no doubt passed into the duodenum. If this portion is carefully examined it will be noted that it is much firmer than the body of the mass. No doubt this is due to the contractions of the pyloric sphincter. Another feature is that this extension projects backward, as though it might have been thus

twisted by the gastric contractions or in adjusting itself to the shape of the first inch or two of the duodenum.

The tumor is six inches in its long diameter, while a tape carried from the pyloric tip to the summit of the cardiac extremity measures eleven and three-quarters inches. Its breadth is two and one-half inches, its thickness two and one-quarter inches. Its longitudinal circumference is thirteen inches; its transverse circumference at the point of deepest notching seven and seven-eighths inches. It weighs fifteen ounces. I am able to present a photograph of the exterior of the mass, which is of the exact

Fig. 2. Hair-cast removed from human stomach. Section; not quite full size.

size of the hair-cast. On section it is seen to be made up almost entirely of hair. There is an occasional bit of string. I submit also a photograph of the cross section. It is, however, not full size.

Hair-balls are frequently found in the stomachs of various animals. Dr. Gull[9] describes in an interesting way the habit the angora cat has of swallowing his hair when shedding his coat. I submit for inspection a hair-ball taken from the stomach of a cow, and another from that of a pig. Works on veterinary surgery in referring to this habit speak of animals licking themselves and each other, and, because of the roughened surface of the tongue, gathering up stray hairs which in the end accumulate in the stomach. These masses are called bezoars, or, if composed entirely of hair, trichobezoars. They are apt to become coated with lime salts.

Some very interesting superstitions have been connected with these accumulations. Gresswell in his work on "Diseases of the Ox," states that at one time they were presumed to possess the power of enchantment against the viper and the scorpion, against vertigo, epilepsy, dysentery, inflammation of the lungs, malignant fevers, the plague, leprosy, and many other maladies. I quote these lines from him: "It was put down to the astonishing power of the bezoar that King Edward IV. was strengthened and preserved from the effects of an empoisoned wound; and the same magical influence was supposed to be the real reason why Emperor Charles V. was enabled to free himself from the dreadful thoughts which haunted and disturbed his mind."

The accumulation of hair in the stomach of the herbivorous animal assumes a form which is, strictly speaking, a "hair-ball." Works on veterinary surgery state that for their formation some foreign substance is required as a nucleus, and that the rotary movement of the stomach

during digestion gives to the mass a rounded form and a spiral direction to the hairs. This can be observed in the hair-balls submitted. The movements of the stomach of the carnivorous animal have been recently more thoroughly studied. Dr. Cannon[21] administered different quantities of bismuth with food, and, after giving it to a cat, made a series of X-ray pictures of the stomach while the process of digestion proceeded. It appears that the food is crowded onward from the cardiac to the pyloric end by rapidly recurring peristaltic waves, and that the stomach-contents, when filling this organ, are compressed by its muscular contraction and perfectly molded, to conform with the interior of this organ. And so we must assume that when a foreign substance like hair, incapable of digestion, steadily accumulates and ultimately fills the human stomach, it is similarly acted upon and receives the imprint of the contracted organ. Instead of a "hair-ball," we have therefore a "hair-cast" of the stomach.

I have been able, in reviewing the literature of this subject, to find no less than nineteen authentic cases in which a sufficient quantity of hair had been swallowed by individuals to create within the stomach a hair-tumor. These I have arranged chronologically at the end of this paper.

The first recorded case[1] dates back to 1779. It is the only one in which a male was guilty of this habit. He was a boy, sixteen years of age, who seemed unable to resist the impulse to pull out and swallow his own hair and that of others. Not only was a hair-tumor seventeen centimeters long found in his stomach after death, but enough more hair had been swallowed to form a second tumor, twelve centimeters long, which had lodged in the duodenum. In the report of Dr. Ritchie's case[3] a mass of hair is pictured which conforms to the shape of the stomach. Two other hair-balls, weighing respectively one-half ounce and one ounce and a half, were found in the ileum. These had caused intestinal obstruction, perforation and death. In a third case the coexistence of a gastric and duodenal hair-cast is recorded. This, presented by Mr. Pollock[4] to the Pathological Society of London in 1851, is well illustrated in the volume of transactions of this Society for 1851-52. They were removed after death, from the body of a woman eighteen years of age. That taken from the stomach had a length of six inches, a width of three and three-quarters, and a thickness of two and one-half inches. The duodenal mass extended into the jejunum. It presented a length of fourteen inches, a depth of two and one-half inches, and a thickness of two and one-quarter inches.

Why hair taken into the stomach should cling to its walls can be readily imagined. One would think that it could not be easily gotten beyond this viscus. There is a single instance recorded in which an accumulation of hair became lodged in the small intestines and produced intestinal obstruction. No hair was found in the stomach. This case was recently reported by Dr. G. W. W. Brewster[20] in the *Boston Medical and Surgical Journal*. A sausage-shaped tumor presented itself in the region of the bladder. The patient, a girl of ten, survived the operation of enterotomy for its removal only five hours.

The youngest patient was ten years of age, the oldest, thirty-four. Most of the victims of this habit were in their second decennium. But three were married women. None were insane and but few sufficiently nervous to be described as hysterical.

In nearly every instance the habit of hair-swallowing was of years continuance. Once it had existed thirteen years[15]; in another, fifteen[6]; seventeen years in a third case[7], and twenty-two years in a fourth[5]. During this period the stomach gradually became accustomed to the presence of the foreign body, and tolerated it in many instances without the slightest rebellion. One of the largest masses discovered, which weighed four pounds and seven ounces, was reported by Russell[7]. To use his own words: "I may also repeat the statement that the history of the patient did not present any evidence of difficulty in digesting food." One still larger was successfully removed by operation[14]. Its weight was five pounds and three ounces. There are others weighing more than the specimen which I present.

In animals it is not unusual to find a number of hair-tumors at the same time in the stomach. One writer speaks of as many as nine. In but a single case[7] do I find the presence of two recorded as coexisting in the human stomach. These were so molded to each other that together they formed a perfect cast of the stomach. As to form, nearly all present the same picture. With but a single exception they had a pyloric prolongation extending into the duodenum. This case is reported with illustrations by Schoenborn[10] in Langenbeck's Archiv. One case presented an esophageal spur[6]. In Bollinger's case[18] the duodenal projection was fourteen centimeters long and five centimeters thick.

Of the nineteen cases, ten were discovered postmortem, and nine upon the operating-table. It is very surprising that in every instance the discovery of the hair-cast was unexpected. In not a single case had a correct diagnosis been made. And what is still more remarkable, no physician or surgeon had ever surmised that he had to deal with a foreign body in the stomach. Perhaps we should except Stelzner[17] who knowing of Schoenborn's case, suspected that this might be the condition. As a rule the diagnosis was splenic or omental tumor, movable kidney, or fecal or other impaction in the transverse colon. Two of the patients were pregnant. In each of these the vomiting was most intense. In one there was such severe hematemesis that the physician reporting the case was called in consultation to arrest the gastric hemorrhage[7].

The patient's condition was so extreme that she died of collapse on the following day, having in the meantime aborted. In the other case[9] death from perforative peritonitis followed the delivery of a seven-months child. In a few instances vomiting frequently occurred after meals, this having kept up for several years. Occasionally the patient would vomit several times in one day and then not again for several days. Nor was it always food which was ejected. In some instances it was glairy mucus, which would occasionally be streaked with blood. The appetite was variable. In one case[9] hot foods caused pain and vomiting, while cold food could be easily retained. In some instances there was no pain until, as a result of perforation of duodenum or stomach, peritonitis occurred. Others had occasional pains after eating.

In only one instance[10] do I find the peculiarity referred to in my own case, namely, the regular recurrence of severe pain at night and while the patient was in a recumbent posture. This certainly is a manifestation which one should not have with movable kidney, splenic or other tumor. The bowels acted irregularly; more often than not the stools were liquid. In at least one case there was alternating diarrhea and constipation[15]. In a few there was suppression of menstruation. The general condition of the patient was sometimes not much altered. In other cases there were marked emaciation, anemia, or as occurred in my own patient, a condition of immaturity, for, as will be recalled, though eleven years of age she appeared to be scarcely more than seven.

Almost without exception the discovery that the patient had been a hair-eater was not made until the tumor was found. As a rule the hair had been simply bitten off from braids or flowing locks, but in other instances hairs of great length were found. One woman[7] is said to have pulled the hair out of the back of her head whenever she became nervous, rolling it up into a ball and swallowing it, while another deliberately swallowed her combings night and morning[8]. In a single instance the hair came from a foreign source; Schultén's patient—a weaver of cow's hair into shoes—frequently, while at work, carried her hair-covered finger to her mouth.

The physical signs as stated were always incorrectly interpreted. In most instances the tumor occupied the position in the epigastrium described in my own case. It was difficult or impossible to reach the upper border of the mass because of its concealment behind the lower ribs on the left side. In the case of Russell[7], the large tumor so displaced the stomach that it assumed a nearly vertical position, and the pylorus was made to occupy a site in the pelvis. The tumor was always movable, rarely sensitive, although occasionally tenderness was noted. The convex lower surface, the concavity above, gave the mass a striking resemblance to a kidney. Schoenborn and Naunyn[10] studied their case very closely. They introduced a tube into the stomach and inflated this organ. As the viscus became distended the anterior wall of the stomach was elevated and the mass was made to occupy a deeper position. They were both quite convinced therefore that the tumor was a misplaced kidney.

In nearly every fatal case death resulted from perforative peritonitis. In some cases the mucous membrane and muscular coat of the stomach were found greatly thickened. The perforating ulcer had no fixed location. It was found situated in various parts of the stomach, and in at least one case was in the duodenum[9].

While it must be admitted that in the nine operated cases the surgical procedure was intended to be only an exploratory one, or was performed with the expectation of finding other conditions, it is a matter of great gratification that in every instance the patient made an uninterrupted recovery. Not a single death attended the operation.

The first reported case in which laparotomy was successful was by Schoenborn in 1883[10]. Soon thereafter (1884) Thornton[11]* operated upon his patient. The other gastrotomies were performed by Berg[12], Swain[14], M. W. af Schultén[15], Allen[16], Stelzner[17], Schopf[18], and myself[19]. With the exception of Schopf[18] each operator removed the mass entire. In most instances silk was used as suture material. In all cases total disappearance of symptoms occurred after recovery from operation.

Addendum.—Soon after I read this paper at the meeting of the Medical Society of the State of New York, Dr. Wm. Finder of Troy called my attention to a specimen presented by himself to the New York State Medical Association at its annual meeting in 1886 and which he informs me is now in the Museum of the College of Physicians and Surgeons of New York. There were two masses, together weighing sixteen ounces and composed of human and horse's hair, sewing-thread, grasses, and plant fiber. These were removed postmortem from the stomach of a young woman in March, 1886, who was supposed to have died of malignant disease of the stomach.

SCURVY AND RICKETS IN YOUNG CHILDREN.

By H. A. HARE, M.D.,
OF PHILADELPHIA;
PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE; PHYSICIAN TO THE JEFFERSON MEDICAL COLLEGE HOSPITAL.

It has only been within the last decade that the possibility of scurvy occurring in young children has been generally recognized by the profession. Prior to that time we were wont to consider that scorbutus was a disease which was prone to attack seamen placed under unfavorable dietetic conditions, and scarcely to think of the possibility of its occurring in persons living on shore and obtaining a varied diet. Still less did it occur to us that some obscure manifestations of diseases in nursing infants might be due to this cause. During the past decade, however, evidence has been present in considerable amount which shows very clearly that scurvy is by no means a very rare affection in early life, and that it often manifests itself in such a way as to lead the physician to make a very erroneous diagnosis when the patient is first brought to him.

Perhaps the most frequent error in diagnosis under these circumstances is that the child is suffering from muscular or articular rheumatism; this decision being reached by reason of the fact that the child seems to suffer great pain upon movement, and sometimes has a small degree of fever. The pain on motion is so excessive in many cases as to seem almost agonizing; and it is by no means uncommon for parents to permit children to become excessively unclean because the movements necessary in bathing cause such manifestations of pain that it seems a greater kindness to permit the child to become filthy than to move it about. As a matter of fact, acute articular rheumatism in young children is a very uncommon disease, certainly while they are still nurslings, and particularly is this true of most portions of the United States where rheumatic fever is by no means as common as it is in England and perhaps some other portions of the Old World. While it is true that acute articular rheumatism frequently attacks children in the second decade of life, it is equally true that it is rare, as we have just stated, in the first five years of existence.

The characteristic symptoms of scurvy in a young child, when they are well developed, are so pathognomonic that it is difficult to see how an error in diagnosis can be made if the physician is acquainted with the possibility of the occurrence of this disease. Like all diseases, however, instances are met with in which many of the characteristic symptoms are entirely absent, and it is not uncommon for the painful manifestations that we have spoken of to be the only evidence of the malady. In still others, we find a peculiar spongy state of the gums, which tend to bleed when lightly touched and which are frequently so swollen that teeth which have recently broken through the gum are speedily covered in by the overgrowth of the mucous membrane, the edges of which, about the teeth, frequently look as if they were composed of tiny blebs of blood of a dark color. The other symptom of scurvy, which is by no means as constant and yet which is equally characteristic, when it occurs, is the development of petechiæ in different portions of the body, very frequently about the ankles and feet. In still other cases, subperiosteal hematoma develops with surprising rapidity, and, as pain on movement and the development of great swelling are frequently first noticed after a fall or a blow, it not rarely occurs that the physician is led into the belief that traumatism is the cause of the illness, without recognizing the fact that it has played but a small part in causing the sudden development of a state which really indicates grave systemic conditions. It is true that these subperiosteal hematomata have been chiefly reported by French clinicians, and have been rarely seen in this country, whereas, on the other hand, considerable extravasations of bloody serum have been met with in the loose tissues after exposure to injuries which in the healthy infant would produce no symptoms whatever. Particular attention has recently been called to these cases of scurvy simulating rheumatism by Griffith, of Philadelphia, in a paper which he read before the County Medical Society.

The peculiar characteristics of scurvy in infants are the very grave appearance of the child when suffering from the disease in its severe forms, the rapidity with which it improves under proper treatment, and the rarity with which death occurs as the direct result of the malady, since a fatality is usually produced by some intercurrent disease which speedily saps the vitality of a child whose vital resistance is already so impaired.

The following cases illustrate three types of this condition which have come under my observation: The first occurred some years before scurvy was recognized as a common disease in early infancy and was that of a child, about a year old, who cried bitterly every time it was moved, particularly if the movement in any way involved a change in the position of its back. Indeed, the back symptoms were so marked that the father of the child, a physician, called me to see it in order to determine whether it was suffering from spinal disease, and I, in turn, asked for the opinion of a well-known orthopedic surgeon, who stated that spinal disease was present, and who prescribed a line of mechanical treatment which chiefly consisted in fixation of the spine and abso-

lute immobility of the body as far as possible, with the object of avoiding pain and lessening irritation. After this treatment had been kept up for a considerable period of time without any benefit taking place, except that the child had been free from the suffering incident to the frequent moving of its body, it occurred to me that this might be a case of infantile scurvy, and in following out this idea it was promptly treated for this condition, with an amelioration and final cure of its symptoms which were extraordinary in their rapidity.

Another case was that of a child in the northern part of Philadelphia, seen in consultation with a well-known practitioner, who gave me a history that three other children of the family had died in early infancy with symptoms which had been variously described as meningitis, cerebrospinal meningitis and "spinal trouble." The parents were much alarmed because they thought that the present infant was manifesting the same symptoms which had carried off the other children. This child screamed incessantly, night and day, and nothing seemed to comfort it. The more it was nursed and coddled, the more its parents tossed it up and down and walked with it, the louder became the cries of the child; yet its crying was so incessant when it was laid in its crib or upon a bed that the members of the family took turns in keeping it in their arms, day and night, until all of the adults of the family were exhausted, and the child also seemed to be on the verge of collapse. Careful examination of this child revealed the fact that its gums were slightly spongy, and as no evidences of disease in its spine or joints or head could be demonstrated, the diagnosis of probable scurvy was made, and proper treatment again resulted in a very extraordinary rapidity of cure, the pain ceasing and the child becoming quiet and sleeping naturally under a proper dietetic arrangement when the use of bromides and other sedatives in ordinary doses had failed to produce any marked change for the better, even of a temporary character.

The third case was that of a child of wealthy parents who suffered at the end of its first year of life with almost complete paraplegia. It was plump but pallid, and its gums and mouth presented the characteristic scorbutic symptoms already named, so that in this instance the diagnosis was by no means difficult. The possibility of scurvy had not been thought of, as the child was supposed to be fed on the best cow's milk that money could buy, with the addition of a well-known form of artificial infant's food. Here again the introduction of proper dietetic regimen resulted in an equally speedy cure with total disappearance of the paraplegic symptoms and a recovery of power in the lower extremities which was remarkable. No one who had not had experience with such cases would have believed that so much loss of power could be so soon followed by its complete reinstatement.

I wish to conclude this brief paper by pointing out a feature of this disease which has seemed to me to be quite constant, namely, that scorbutus in infancy is distinctly a disease of the children of the well-to-do in distinction from rickets which, on the other hand, seems to be a disease of the poor. Clinical experience, I think, indicates that scorbutic cases are rarely brought to hospital dispensaries while rachitic cases are constantly seen. On the other hand, scorbutic cases are not uncommonly met with in private practice. This clinical fact seems to carry out certain theories which have been advanced in regard to rickets in a way which is interesting. It is not many years since every one believed that rickets was due to a deficient quantity of bone-forming material in the food of the child, but since that time other clinicians have stated their belief that more commonly it depends upon inability of the child to assimilate and utilize the ingredients in its food which it needs for proper bone growth. Or, in other words, the fault lies not with the food but with the child. Amongst the poor this inability is probably due to unhealthy surroundings and a general lack of sanitation which interferes with development. On the other hand, such influences are not at work among the children of the well-to-do, but these children often receive, for long periods of time, the various artificial foods which, in many instances, they are incapable of digesting, and not only this, but no change is made in their diet for months, either in the quantity of the various ingredients which it contains, or in their quality. These children, therefore, suffer from the nutritive changes which come on as a result of a limited and fixed diet with no variation; whereas, the children of the poor, who often have too great a variation in their diet, rarely present scorbutic symptoms and often do manifest distinct rachitic symptoms.

It is known that not rarely cases of laryngeal spasm or cough depend upon either rickets or scorbutus, probably most commonly, the former, though in one or two instances excessive laryngeal irritation has been met with by me in children who were distinctly scorbutic. It would be well if physicians in the presence of obscure cases occurring in early childhood would remember the possibility of either one of these affections being the underlying cause for the manifestations of disease and thoroughly investigate the question of diet before administering remedies, such as the salicylates for rheumatism, iron for the blood, or bromides for nervous irritation. It seems hardly necessary to add that, when artificial foods have been largely employed and scurvy has developed, they should be cut out of the diet list; that natural food should be largely introduced; that orange-juice should be freely given, and that beef-juice should, for a time at least, form an important part of the child's food. It is quite extraordinary in some cases to note the almost instinctive avidity with which little babies, too young to have any real desire for a particular kind of food, will seize upon a spoonful of beef-juice and apparently enjoy its taste, as if appreciating the value of this fluid to the economy.

THE RELATION OF TUBERCULOSIS TO THE TENEMENT-HOUSE PROBLEM.[1]

By ARTHUR R. GUERARD, M.D.,
OF NEW YORK;
ASSISTANT BACTERIOLOGIST OF THE NEW YORK CITY DEPARTMENT OF HEALTH AND INSTRUCTOR IN MATERIA MEDICA AND THERAPEUTICS IN THE NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

In view of the fact that tuberculosis, although not by any means confined to the tenements, finds its chief centers of infection and makes its greatest ravages in these districts, the Tenement-House Commission, appointed to examine into the conditions of life of the poor in New York State, has undoubtedly shown a true appreciation of its important duties in deciding to devote its first public hearing in this city to a discussion of the momentous question, The Relation of Tuberculosis to the Tenement-House Problem.

When it is considered, however, that, according to the statistics of the Department of Health, between eight and nine thousand deaths from pulmonary tuberculosis are annually reported in the Greater City of New York—I say *reported* advisedly, for the actual number of deaths from this cause probably far exceeds the figures given—and when it is estimated that at least four times this number of persons at present suffering from phthisis in a more or less advanced stage of the disease are now living in the city, perhaps three-fourths of which, or in the neighborhood of twenty thousand, are to be found in the tenement-house districts, the immense magnitude and difficulty of dealing with this problem may be readily realized.

It has been suggested, as the best and only radical solution of the problem, that public hospitals and sanitoria should be established for the isolation and treatment of the consumptive poor; but as useful and necessary—nay, urgently needed—as such institutions are, as an adjunct to the methods to be adopted, it is manifestly impossible to care for the vast multitude of tuberculous individuals in this way. We must, therefore, depend chiefly upon other and more general means for the restriction of tuberculosis, if we can ever hope to prevent it and finally drive it from our midst. We must continue to improve the general health of our cities by judicious sanitary measures, we must better the condition of the poor by the erection of suitable tenement-houses and by gradually educating the people in the ordinary laws of hygiene, so that they may be able to take better care of themselves and their families; and above all we must warn the public of the dangers of contracting consumption, how to prevent it and avoid communicating the infection to others.

Tuberculosis, as is now generally known, is caused by the tubercle bacillus, a specific germ, without which the disease cannot be produced. But it is important to bear in mind, not only with regard to consumption but all other bacterial diseases, that the mere presence of the microscopic organism in the body does not cause disease when the conditions in which the germ can grow and develop its poison are absent; it is only when the conditions favorable to its growth exist that it becomes a harmful invader. Thus, although the bacillus tuberculosis is the essential cause of this infectious disease, there are various other contributing causes which influence the production of tuberculosis, and unless these causes are at work, weakening and exhausting the vital functions, the tubercle bacillus, when present, meeting with a sterile soil and the natural resistance of the body in health to all disease, although otherwise a most destructive and insatiable tissue-consumer, soon dies of inanition, or, at any rate, remains quiescent and harmless.

It is to the unfortunate existence of unhygienic conditions, which favor the growth and development of this ubiquitous bacillus in the habitations of the poor, that the prevalence of tuberculosis in the tenement-house districts is due. One of the most potent factors in the production of consumption, especially in the tenements, is overcrowding and consequent foulness of the air. "The respiration of impure air," says one great authority on tuberculosis, "directly debilitates the vital powers, enfeebles the nervous system, depresses the appetite, deranges the secretions and leads to the retention of effete matter in the blood." It has been repeatedly observed that previously-inhaled air is one of the main causes in the production of phthisis. "With the fear of bacilli and contagion before his eyes," says another well-known authority, "neither the patient nor his attendant will hesitate to ventilate sufficiently, and constantly renew the air breathed. *Free extreme ventilation is the most important means of preventing and also of treating pulmonary consumption.*"

I might, if space allowed, quote many striking examples of the influence of deficient ventilation in predisposing to consumption. This influence is most marked in prisons, asylums, workshops and similar places, where vitiated air is breathed continuously, and where other injurious influences are also usually at work. It commonly means that the sufferer follows a sedentary occupation and works in a constrained position, or is confined indoors amid depressing surroundings. In addition he may be underfed, and it is a well-known fact that bad air leads to intemperance; poor food and drunkenness have a special influence in rendering people susceptible to consumption.

The effects of overcrowding are well exemplified in densely populated cities. Lagneau has shown, from statistics collected from 662 cities in France, that the denser the population the greater is the number of deaths from tuberculosis. Thus, while the death-rate per 1000 of the population from this cause in cities of 5000 inhabitants was 1.81, in cities of 10,000 inhabitants it was 2.16; in cities of 20,000 inhabitants it was 2.71; in cities of 30,000 inhabitants it was 2.88; in cities of 100,000 inhabitants it was 3.05; in cities of 450,000 it was 3.63; and in Paris, with upward of three million inhabitants, the death-rate per 1000 of the population rose to 4.00. From the Report of the

[1] A paper presented to the Tenement House Commission at its meeting in New York City, November 16, 1900.

Health of Towns Commission for Great Britain it appears that the ratio of phthisis and other similar diseases in Dundee, Scotland, increases with the overcrowding in dwellings. Taking the ratio of dwellings of four rooms and upward as 10, it was found that the other ratios were: For three rooms, 17; for two rooms, 20; and for one room, 23. The same thing has been observed in London. According to the Annual Report of the Medical Officer of Health in London, 1898, in districts with under 10 per cent. of overcrowding (overcrowding being taken to mean where more than two persons occupied a room in tenements of less than five rooms) the death-rate per 1000 from tuberculosis is 1.10; in districts with under 15 per cent. overcrowding it is 1.43; in districts with under 20 per cent. overcrowding it is 1.61; in districts with under 25 per cent. overcrowding it is 1.80; in districts with under 30 per cent. overcrowding it is 2.07; in districts with under 35 per cent. overcrowding it is 2.42, and in districts with over 35 per cent. overcrowding the death-rate per 1000 from consumption is 2.63. Similar observations conducted for the four years previous to 1898 showed the same obvious relation between the amount of overcrowding and the phthisis death-rate.

It has also been repeatedly observed that some houses in these overcrowded districts after a time seem to become permanently infected with tuberculosis, as evidenced by a repetition of cases of the disease. There can be but little doubt that in many instances such a "family house" is a far more important factor in the production of consumption than any supposed "family predisposition," these houses becoming infected through the poisonous discharges of previous tuberculous inmates. It is easy to understand how the permanent infection of premises may occur when one considers that the sputum of consumptives, which frequently contains a countless number of virulent tubercle bacilli, is often carelessly expectorated on the floor and elsewhere in dwellings, where it dries and is converted into dust, thus getting into cracks in the woodwork, in the papering, etc., whence it is later inhaled into the lungs by others. Such tuberculous dust has been found by experiment to remain virulent and infectious for months and even years after it was deposited in rooms which were not thoroughly disinfected and renovated; and where this dust is allowed to accumulate for a length of time it may be impossible to disinfect and renovate the premises without practically rebuilding them. These premises then become permanently infected.

From an investigation made by the writer in 1897, from the maps and records of the Department of Health, into the distribution of tuberculosis in New York City, it was found that in two wards of the city (Wards IV and VI) 38 per cent. of the total number of dwellings had cases (including deaths) of consumption reported from them during the years 1894, 1895 and 1896. Of these cases one-half occurred in 23 per cent. of the affected houses, this being but 9 per cent. of all the dwellings in the wards. One-fourth of the houses had apparently become permanently infected, as shown by a repetition of three or more cases of consumption in them in the three years, while certain very bad houses had eight or more cases repeated in them. During a period of eight years previous to 1897, according to the records, 136 cases of pulmonary tuberculosis (including deaths) were reported from twelve houses, or an average of 11⅓ cases per house. And these were only the reported cases and deaths, which, as we know, represents but two-thirds to one-half of the actual number of cases which probably occurred in these houses. It may be safely estimated, therefore, that 200 or more cases of consumption, or an average of about 20 per house, had occurred in these twelve houses in eight years—a truly startling exhibition.

These two wards were selected for study because they contained a large number of tenement-houses in one of the most overcrowded parts of the city, and because they illustrated most forcibly the effects of overcrowding and consequent foulness of air. The greatest prevalence of the disease was found in those tenements in which the sanitary provisions were most deficient, especially in rear houses and old, dilapidated buildings, where lack of ventilation and light and the presence of ignorance, poverty and filth furnished the most favorable conditions for the growth of all bacteria, and especially of the tubercle bacillus. These conditions have since been partially removed by action of the Department of Health and some of the most unsanitary houses were condemned and torn down in 1896; but many other equally-infected tenements in these and other parts of the city are still standing, some of them having shown an increased repetition of cases—a menace to the health of the community—despite all possible efforts toward disinfection, renovation, etc., on the part of the sanitary authorities.

Analogous investigations have also been made by others in this country and abroad with the same result. Dr. Ransome found in Manchester, England, that tuberculosis was distinctly more prevalent in certain houses than in others. The closed courts and alleys, the shut-in or blocked-up houses, and, above all, the houses built back to back, with no through ventilation, and with bad light, were the most affected. In some instances, within five or six years, double or treble occurrences of the disease had taken place in the same house, and some houses not only showed a repetition of cases, but patients who had improved on being taken to hospital had a recurrence of severe tuberculous symptoms when they returned home, and had to be sent to hospital again. Dr. Tracy, Registrar for the City of New York, has also studied the distribution of tuberculosis throughout the entire city, from the record of deaths during the five years, 1888-1892; and Dr. Flick has done the same for one ward in Philadelphia for twenty-five years previous to 1888. The conclusions arrived at by these competent observers tally exactly with those reached by the writer, *viz.*, that

tuberculosis is not uniformly diffused throughout a community, not even in those localities where the disease is most prevalent, but is confined within narrow limits, as in certain streets and within the walls of certain houses.

That this effect is largely the result of deficient ventilation and lack of pure air and light there can be no doubt, although, of course, other conditions to be found in the tenement-house districts also take part in the production of the disease. As to the effect of light, there is abundant evidence to show that daylight, especially direct sunlight, exercises a beneficial influence in maintaining the general standard of health; and that darkness and damp tend to produce disease. It has been proved by numerous experiments that light is inimical to and under favorable circumstances may wholly prevent the development of bacteria and disease-producing organisms. The tubercle bacillus when exposed to direct sunlight is killed in from a few minutes to several hours, depending on the thickness of the layer and the season of the year; and when placed in diffuse daylight, as near a window, it is destroyed in from five to seven days. No dark or damp dwelling is fit for human habitation, and those who live in such places are seen to grow pale, sicken and die, like plants that are kept in a cellar.

There is an Italian saying to the effect that where the sun does not enter the doctor does, and the Indians have a proverb which says that he who plants a tree in front of his house begins to dig his own grave. The value of sunlight in the treatment of consumption, especially in its early stages, has long been recognized by practical physicians, and the method which has been most successful in curing the disease, and which is now practised generally in sanatoria for consumptives, consists chiefly in a plentiful supply of sunlight and fresh air, together, of course, with the necessary rest, proper food, medical and hygienic treatment, patients when suffering from tuberculosis being placed on a terrace in the open air or in a balcony sheltered from cold winds, but exposed for many hours during the day to the full direct rays of the sun.

Another no less important predisposing cause of phthisis is habit of life and occupation. It has been observed that those who follow an outdoor life under normal healthy conditions are comparatively free from the disease, while those who lead sedentary lives, habitually indoors, are very subject to consumption, the maximum incidence of this affection being found among persons who constantly inhale impure air in badly-ventilated rooms and in occupations associated with a dusty atmosphere. Thus stone-cutters, knife-grinders, potters, plasterers, dyers, wood-carvers, cigar-makers, polishers and the like suffer particularly from phthisis. Printers, compositors, tailors, dressmakers, bakers and all those who work in a constrained position in poorly-ventilated, poorly-lighted or damp places, or where smoke and various irritating gases are generated also readily contract the disease. And how many of our tenement-house dwellers do we find working at such occupations under bad hygienic conditions!

But admitting that these evils, and others conducive to tuberculosis, exist in the tenement-house districts, what can be done to ameliorate or remove them? The problem is unquestionably a difficult one—probably the gravest and most difficult of the day, and as such it is worthy of the consideration of all thoughtful men—but, although it may take a long time and the expenditure of much money to solve it, I do not think that it is hopeless of solution.

Apart from the erection of public hospitals and sanatoria for the care and treatment of the consumptive poor, which we need not consider here, much might be done in the way of legislative enactments regulating the width of the streets of cities, the construction and height of the houses, and, above all, the preservation of parks or open spaces. The establishment of public washhouses would have a very beneficial effect in minimizing the frequency with which washing and drying of clothes is carried on in small rooms. In the same way, the evils resulting from working at home at sedentary occupations in ill-ventilated apartments might to some extent be obviated by the establishment of public workrooms, where, on payment of a small fee, tailoring, shoemaking and other similar employments might be followed; and it would be well if all such deleterious home-work were prohibited. The erection of model tenement-houses, constructed on true hygienic principles, by generous and liberal-minded private individuals, is a noble and far-reaching charity and is much to be commended; and could municipalities undertake such a work it would prove to be an investment which, both directly and indirectly, would return a handsome interest. The building of cottage homes on the outskirts of cities, together with cheap rapid transit facilities, for re-housing the working classes on the destruction of unsanitary tenements in the congested districts, is also to be encouraged, and this would afford, perhaps, the most practical means toward a final solution of the problem.

Meanwhile the overcrowding of tenements should be restricted by regulating the air-space, allowing not less than 600 cubic feet to each adult and 200 cubic feet to each child of five years, and by enforcing the ventilation and lighting of rooms by means of a current of air from windows opening upon the outer air, or at least upon large air-shafts. Undoubtedly all back-to-back and rear houses should be absolutely condemned. Not only should the height of new houses be regulated according to the width of the streets, but the erection of additional stories to houses already standing on narrow streets should be forbidden. In a city like New York, where the price of building lots is ever on the increase, the natural tendency is to make the houses higher and higher, until in many of them the amount of daylight which reaches the rooms on the ground floor is so small that only the upper stories are fit to live in, the rooms in the lower stories being too dark and damp for anything but

an abode for rats. Sufficient air-space should be left behind the houses to allow thorough ventilation; nor should the corner houses be permitted to cover the entire lot; and streets should be open from end to end, so that all houses have free ventilation both back and front.

Every landlord should be required, before letting his tenements to different families, (1) to make ample and suitable water-closet provision for the number of persons who are to occupy the houses, preferably a separate water-closet to each set of apartments; (2) to supply each set of apartments with a separate water-supply and bath—cheap public baths are a fair substitute, but there is nothing like a private bath to encourage cleanly habits; (3) to provide separate storage for coal; (4) to provide sufficient means for washing clothes; and (5) to provide pantry accommodation for the keeping of food. These are not luxuries, but absolute necessaries of life for civilized beings, and therefore should be provided in every tenement. Their presence tends to promote health; their absence causes dirt, ill-health, disease and death, while it also tends to dehumanize people and to breed paupers and criminals. If we cannot prevent the aggregation of population in cities, we should at least try to make the evil effects of overcrowding as little felt as possible.

The results of injurious occupations in factories, workshops, etc., have already been greatly mitigated by the introduction of improved machinery and methods, by the regulation of hours of work, by prohibiting the employment of very young children, and by enforcing the use of fans to carry off the dust and deleterious gases, but there is still room for improvement in these matters.

Much has been done by the sanitary authorities as pioneers in the crusade against consumption, by the adoption of improved measures of sanitation, by the enforced disinfection and renovation of infected premises, by the compulsory notification of tuberculosis as an infectious and communicable disease, by the prohibition of spitting in public places and conveyances, and by the distribution of circulars of information regarding the nature of consumption. These laws and regulations should be more rigorously enforced, and especially by every means in our power—through societies for the prevention of tuberculosis and through the press, the pulpit and the schools, as well as through boards of health—we should endeavor to educate the public as to the character of this disease, more particularly with regard to the danger of communicating the malady through the expectoration of consumptives unless this is received in proper receptacles and destroyed before it can dry and mingle with the dust. And by flooding the cities, especially tenements, workshops, schools and stores, with simple notices of these facts, we should keep on advertising them, so to speak, on the highways and byways, until, like other advertisements, they are read and remembered.

But it may be asked, will it pay to do all this? The Anglo-Saxons are frequently called "a nation of shopkeepers," and we Americans particularly are said to "worship the Almighty Dollar." Some time ago I attempted to estimate the pecuniary loss to the community, as the result of the mortality and disqualifying power of consumption; and perhaps this estimate is worth recalling in connection with the relation of tuberculosis to the tenement-house problem.

It is not easy to place a money value upon human life, but, according to one of the best authorities on this subject, the economic value of the individual is what he has cost his family, the community or the State for his living, development and education—the loan, as it were, which the individual has made to him to reach the age when he can restore it by his labor. The average life-value has been estimated by different economists in Europe at amounts ranging from $750 to $1000, and over; and the law often allows far larger sums than this for loss of life and limb. It is certainly not an overestimate, therefore, to place the pecuniary life-value of a citizen of New York at $1000. Now there are, according to the official records, over 8000 deaths per annum at present in New York City due to pulmonary tuberculosis alone, and at least 7300 of these, or about 91 per cent., occur between the ages of fifteen and sixty-five, that is during the period of the greatest productive capacity of the individual. Thus taking $1000 to be the value of adult human life in this city, and the annual mortality from consumption of persons between fifteen and sixty-five years of age to be 7300, there would be an actual yearly loss to the community from this cause of $7,300,000. But a sufferer from this disease is usually incapacitated from work for a considerable period before his death, during which time he earns no wages, and a corresponding loss in producing power thus accrues to the community. Many consumptives die within the first few months and, from this point of view, influence the question comparatively little. Others again live for a number of months and some for several years. It is possible that a few of these are in the full exercise of their power and that their earning capacity is unimpaired; but the majority are in all probability burdens on their relatives or on the city. Assuming, however, that the average consumptive is incapacitated from active work for three months or ninety days only, and estimating the daily wages of the common laborer to be $1.50—the average number of deaths from consumption between fifteen and sixty-five years of age being 7300—there would be a further loss to the community in productive capacity of $985,500 per annum. Computing these amounts, and leaving out of consideration all other possible expenses connected with the illness and death of the individual, we find that there is at least a yearly tax of $8,285,500 levied in New York City by this dread disease. In this calculation, however, only the reported deaths are considered; whereas at least 30 per cent. more should be added to these, which although reported as due to some other disease are really

tuberculous. There are, moreover, at a conservative estimate not less than 20,000 cases of well-developed and recognized pulmonary tuberculosis now in the city, and an additional large number of obscure or incipient cases. If we include these two classes, a considerable proportion of which are doubtless also incapacitated from work, we may safely estimate the annual pecuniary loss to the community from consumption to be little short of ten million dollars. And the greater part of this loss, remember, occurs in the tenement-house-districts, *i. e.*, among those who furnish the real physical strength of the nation.

Taking, therefore, only a sordid view of the matter, it will certainly pay to expend money and time in the effort to check the ravages of a disease which causes such an enormous financial loss that it is incalculable. But tuberculosis does more than this: It not only gives rise to a greater loss of life and money in the world than war, pestilence or famine, but it is the source of more misery, suffering, poverty, and perhaps crime, than all the other ills to which human flesh is heir.

And yet there is no doubt that this is a preventible disease and can be more easily prevented, with our present knowledge of its origin and nature, than cholera, smallpox or the bubonic plague—other bacterial diseases which in the Middle Ages, under the name of "the Black Death," decimated the populations of the earth, as the result of still more unhygienic conditions and of greater ignorance, poverty and filth, but which now have been entirely rooted out from all civilized countries, because the necessary sanitary precautions were taken to prevent them.

Tuberculosis, although an evil much to be dreaded, is not an inevitable decree of Fate, not an unavoidable disposition of Providence, as it has been commonly thought to be; but like many other ills from which mankind unhappily suffers, the remedy for it exists to a great extent in ourselves:

> "Our remedies oft in ourselves do lie,
> Which we ascribe to Heaven: the fated sky
> Gives us free scope; only doth backward pull
> Our slow designs, when we ourselves are dull."

The skeptics tell us that to hope to eradicate tuberculosis is the dream of sanitary enthusiasts, far-fetched and Utopian. But already the mortality from this disease has been much reduced, owing to the adoption of improved sanitary methods, although carried out on a limited scale and in an irregular manner. May we not reasonably assume, then, that more vigorous and systematic measures, together with organized and cooperative action, will accomplish infinitely better results? This is an age of combinations, unions and alliances of all kinds. Why should we not combine the vast interests of doing good in this great work of practical sanitation, with the full belief and expectation that the day will come when this wide-spread and fatal scourge may be completely exterminated?

A table showing the mortality from phthisis at various ages and between the ages of fifteen and sixty-five, the total mortality from phthisis irrespective of age, and the general mortality, in New York City (Manhattan and the Bronx and Greater New York), for the years 1897-98 and 99, taken from the official records.

	Year	Deaths from phthisis at various ages.							Deaths from phthisis between the ages of 15 and 65.	Total deaths from phthisis irrespective of age.	Total deaths from all causes.
		0—1	1—15	15—20	20—35	35—55	55—65	Over 65	15—65		
Manhattan and the Bronx	1897	51	146	274	2182	1684	523	185	4463	4813	38,877
	1898	12	134	229	2148	1811	308	223	4588	4957	40,438
	1899	61	162	256	2303	1885	427	241	4771	5238	39,911
Greater New York	1898	60	238	378	3370	2722	558	360	7057	7724	66,294
	1899	98	264	416	3578	2817	522	340	7313	8015	65,343

Note.—It appears from this table that the deaths from phthisis constitute about one-eighth of all the deaths in New York City, and that about 91 per cent. of these occur between the ages of fifteen and sixty-five. Thus, for the years 1898 and 1899, in Greater New York, there were respectively 7724 and 8015 deaths from phthisis, of which 7054 and 7310 occurred between the ages of fifteen and sixty-five, or during the period of greatest productive capacity.

Only pulmonary phthisis or consumption is here considered, this being by far the commonest and most fatal form of tuberculosis and also the most easily preventable

TREATMENT OF LUPUS.[1]

By H. ROCKWELL VARNEY, M.D.,
OF DETROIT;
INSTRUCTOR IN DERMATOLOGY IN DETROIT COLLEGE OF MEDICINE; DERMATOLOGIST TO HARPER HOSPITAL POLYCLINIC.

TUBERCULOSIS of the skin is one of the most interesting of dermatological lesions, not only from its prognosis, but from its common etiology with one of the most fatal and wide-spread diseases of the country. I feel no hesitancy, therefore, in presenting this paper to the general practitioner, and trust, with some clinical illustrations, that it may be of profit.

Long before the discovery of the tubercle bacillus, Friedländer pointed out with clearness a histological resemblance of lupus to tuberculosis in other organs of the human structure, and in lower animals. Lupus, tuberculosis cutis, and scrofuloderma, before the investigations of Koch, were diseases classified as distinct dermatological manifestations, the true etiology of which was unsuspected. At present through the discovery of the tubercle bacillus, they are placed under one common cause, although differing widely in clinical symptomatology.

It is now positively proven by inoculation, microscopical and pathological research, that the tubercle bacillus is the true cause of lupus in its many classifications, except lupus erythematosus in which the tubercle bacilli has not as yet been found and which, therefore, cannot be classified as tuberculosis of the skin. Therefore, tuberculosis cutis is an infectious, chronic disease of the skin and mucous membrane caused by a specific organism, characterized by deep and superficially-seated nodules which tend to absorption, ulceration or cicatricial atrophy.

The wide clinical field of lupus is more clear if we note the site of the tubercle in the tissue in which the infection is located. In scrofuloderma the tubercle starts in the subcutaneous connective tissues, attacking first the glands with deep ulceration, a term used by dermatologists to cover up many sins of the diagnosis in the past.

In lupus vulgaris the tubercles in the corium extend upward with ulceration, but fewer in number, not so large an area is affected as in scrofuloderma, while in tuberculosis cutis the tubercle in any situation grows rapidly and contains large numbers of tubercle bacilli, but with less tendency to ulceration. The pathological morbid anatomy of the tubercle in these affections has the same groundwork and depends upon the activity of the Koch bacillus.

In the treatment of cutaneous tuberculosis we have as yet no specific serum that can neutralize the virus and produce absorption of the tubercle. Our expectations, so brightened by Koch in 1889 with the first reports of the treatment of lupus by its advocates, have gradually faded. With the use of the serum there was temporary improvement, but the pronounced reaction of the serum endangered life and caused its abandonment, and relapse soon occurred. Internal treatment alone has nothing, therefore, to offer, except when the patient's general condition is below par, when the use of internal medications, such as tonics, is indicated; yet many persons afflicted with this disease enjoy the best of health in every other particular.

External treatment may be divided into surgical and mechanical. Excision has been used with good results, but will always meet with objections when the lesions are on the face, since skin-grafting must be resorted to in this method, and healthy skin is often sacrificed and recurrence is common in the new skin.

The most satisfactory surgical treatment in my hands is the curette. With a common dermal curette one is able with but little experience to distinguish readily the healthy tissue from the broken-down cheesy degeneration of the tubercle. In this method one does not destroy bands or islands of healthy tissue, which if left aid far more in healing than the skin-graft which would have to be used in excision. In this treatment it is always best to operate without freezing mixtures, as anesthesia by such mixtures alter the color and texture of the tissues, and thus render it difficult to see or feel the diseased areas.

Linear scarification is a treatment that has been used with success in cases that are new and not broken-down. I have never made use of this method, as it is slow and objectionable.

Electrolysis is advocated by Dr. Jackson, who reports good results in recurrent lesions. I have used his single-needle methods in few cases, all of which have proven very satisfactory. A small galvanic battery is used, one that can be relied upon to give an even current, an epilating needle-holder, platinum needle, and good light are the accesories. The lesion is first sponged with ether, the positive pole is then placed in the hands of the patient, and the negative pole contains the needle and is passed directly into the tubercle. A current of two milliamperes is sufficient, just whitening the tissues without burning them. The needle is swept around in the tubercle for about ten seconds, then withdrawn and passed into the same tubercle from the opposite direction, being careful not to burn epithelium, in which case ulceration and scarring result. The effect of electricity upon the tubercle nodule or lupus is two-fold, the heat destroys the germs and the electricity stimulates cell-changes.

Mechanical treatment consists in the use of escharotics and caustic pastes which will most rapidly destroy the tubercle. Those that meet with most favor are those that will destroy diseased tissue and not have any effect on the surrounding tissues. Nitrate of silver stands first, either in stick form or in solution. Patients prefer it to the knife, although it is painful. It will penetrate and destroy the isolated tubercle, as well as the infiltrated area, will spare healthy tissue, and is unattended with danger.

[1]Read before the Detroit Medical Society.

Arsenical pastes, although more painful than silver nitrate, destroy diseased tissue only. Their action is more rapid, but they cannot be applied to large areas because of absorption. All cases treated by caustics should be seen every twenty-four hours. Many of the stronger acids have been used, but they are objectionable because they destroy healthy as well as diseased tissue. Pyrogallic acid is an exception and possesses an advantage over the others by attacking diseased tissue only, and its use is not attended by any bad results. Whatever may be the line of treatment followed, either surgical or mechanical, one may be compelled to use both methods.

My purpose in presenting the subject of lupus was to bring before the Society a treatment comparatively new, concerning which good reports are reported from abroad, as well as from this country. This treatment is by means of the X-ray exposure. Dr. Pusey of Chicago, in a paper not long ago, reported treatment of grave recurrent lupus and other chronic skin affections. In his experiments he discovered that a number of exposures would blanch the hair, destroy the hair bulb, stimulate nutrition of chronic indurated lesions, and reduce inflammation. Upon these observations, the treatment of chronic skin affections was based.

In passing the X-ray through the spectroscope, one sees at the chemical end of the spectrum a combination of two of the primary colors, red and blue, or ultra violet. It is I believe by the action of the stronger chemical colors that the stimulating influence on the tissues by the rays is produced. This is the same principle as that devised by Finsen, in which he used the ultra violet rays of white light. The results are about the same, except the X-ray is somewhat more rapid in its action with shorter exposures, and larger areas may be treated at one sitting than by Finsen's method, so there must be some similarity in the fundamental agencies of these methods.

The treatment of lupus by the X-ray has many advantages. It is painless, the exposures are short in duration, the area treated may be of any size or location, no scarring from treatment if exposures are properly conducted, the time of exposures is regulated by the density of the rays, and the results are evident with much less scar tissue.

The antiseptic power of the X-ray is as yet unsettled. Some of the investigators say that the tubercle bacilli will thrive under any exposures to the X-ray, while others claim that they are destroyed. I have with me a series of tubes inoculated from a pure culture of the tubercle bacilli. Using two tubes as controls, I exposed all the tubes, one, fifteen minutes, three, a half hour, and two, three quarters of an hour, through the opening of the tube four inches distant. I also exposed two tubes three-quarters of an hour through the glass. All the tubes were placed in the incubator at the temperature of the human body and the cultures examined every twenty-four hours. In forty-eight hours distinct growth was seen in all tubes exposed and not in the control tubes. Since the average time for culture of this germ sufficient to show growth is about six days, a marked acceleration in the growth of the germ was brought about by exposure to the rays; therefore it cannot be said that the action of the rays on lupus lesion is an antiseptic one.

The following case is a typical one, showing the effects of treatment by this means:

Mr. G. was born in Germany in 1834. He emigrated to the United States in 1868, was a painter by occupation and has always been in rugged health. No tuberculosis in family. In December, 1899, he noticed a pimple on his left forefinger which he thought was the bite of some insect; no attention was paid to it, but in a few weeks it became more inflamed, and instead of subsiding it became more irritable. In two months it had increased in size to such an extent that it warranted curettement, and was thoroughly curetted by Drs. Marker and James, and dressed antiseptically. The lesion remained stationary for over two weeks, when the hand began once more to swell and there was infiltration into the deeper structures of the skin with rapid growth.

When I first saw the lesion this was the history: Formalin had been suggested as an antiseptic dressing and the patient was brought into the Alumni Clinic and exhibited and diagnosed as a typical tuberculous lesion of the skin by Prof. Carrier and others. It was announced to the Alumni that this case would be treated by exposures to the X-ray and the result reported. In July, before the exposures were begun, the lesion was covered with ulcerative tubercles, deeply seated. There was a watery discharge and marked induration of surrounding tissues which were much increased in size and were painful.

On July 21st the first exposure of eight minutes was given, the hand being held six inches from the tube; July 23d a second exposure of ten minutes was given after which the patient expressed himself as having less discomfort in the lesion. On July 25th there was another exposure of ten minutes; July 26th the fourth exposure of ten minutes after which there was a noticeable improvement. The inflammation became much less, the ulcers began to fill in from the edges, the discharge grew less and the induration of the tissues began to diminish in thickness. July 27th, a ten-minute exposure; July 30th, a ten-minute exposure; August 1st, a ten minute exposure; August 3d, a ten-minute exposure. After these exposures there was the same marked improvement. The exposures were then discontinued and the lesion healed. In all there had been eight exposures extending over a period of fourteen days. During this course of treatment no dressing was applied to the lesion except the bandage.

There was not any burning or change in the surrounding normal tissues, except slight blanching, slight atrophy, and stimulation of hair bulbs. In all of my skiagraphic and chronic ulcer treatment, I have had no X-ray burns.

A REPORT OF SOME CASES OF ABDOMINAL SURGERY, WITH REMARKS ON THE DIAGNOSIS OF CARCINOMA OF THE CECUM AND THE SURGICAL TREATMENT OF CARCINOMA OF THE LIVER AND THE GALL-BLADDER.

By CHARLES GREENE CUMSTON, M.D.,
OF BOSTON, MASS.

(Continued from page 219.)

THE next case is one of extreme interest and rarity; it is one of carcinoma of the cecum complicated by appendicitis, and, on account of the rarity of malignant growth in this region of the gut, I will ask permission to make a few remarks on the symptomatology of this affection after I have reported the case.

Case VI.—Mrs. C. F., aged forty-one years, was seen in consultation with Dr. Frederick Coggeshall, who gave the following history: Her antecedents were excellent, as well as her family history. Her father, mother, brothers and sisters are all living and in excellent health. About March 1, 1900, Dr. Coggeshall was called to see the patient who was suffering from the typical symptoms of appendicitis; the pulse was of a fair quality at 120, and the temperature was 38° C. (100.4° F.). There was much tenderness in the region of the appendix. The patient recovered from this attack in two days, but in the early part of May a similar and more severe attack occurred, the temperature being about 38.5° C. (101.3° F.) and the pulse ranging about 120. Again she recovered from this attack in a couple of days, but she said that during the interval of the attacks she had suffered considerably from flatulency and a tendency to diarrhea.

On May 20th Dr. Coggeshall removed the appendix which was found somewhat dilated and the mucous membrane in a state of hyperemia. There was a small erosion at one point of the mucous membrane near the tip of the appendix where the latter was adherent to the cecum. The patient made an uninterrupted recovery, but she continued to be troubled with flatulency and constipation while in bed. Two weeks after the operation she went out feeling very well, but within three or four days she again began to be troubled by attacks less definitely marked, but similar to those for which the operation of appendectomy had been performed. The tympanites and colic became constantly more and more frequent, the attack usually ending by bilious vomiting and one or two dark, watery stools. These symptoms were aggravated by being on her feet and would subside after a day's rest in bed. Tenderness over the region of the cecum was now constant, and the pain started from that point radiating toward the umbilicus. After about two weeks of apparent improvement the symptoms returned, and two points in the abdomen now became the special seats of distention with gas, namely, the region of the cecum and of the sigmoid flexure. The pain was now constant, but occurred in spasms corresponding to somewhat rhythmical dilatations with gas of the portions of the bowels just mentioned. The principal seat of pain had now shifted to the hypogastrium and umbilicus, and the patient was becoming weaker and losing flesh, and I was requested to see the patient.

Upon examination I found that by deep palpation of the right iliac fossa a small hard immovable mass could be detected apparently in the region of the cecum. The intestines were greatly distended and the entire abdomen was tympanitic, even in the right iliac fossa. The patient had vomited on several occasions during the three days previous to our visit, and it was with difficulty that a stool could be obtained. The pulse was of a fairly good quality, regular and about 100 to the minute. The tongue was furred, the eyes were sunken and the face pinched.

A diagnosis of intestinal obstruction seated in the neighborhood of the cecum was made, but the nature of the obstruction was a question; still, on account of the previous operation for appendicitis, it was thought probably due to adhesions constricting the gut and operation was advised. This was not consented to at the time, but, as all the symptoms increased in severity and the patient was very rapidly losing ground, five days later I opened the abdomen in the median line.

There was great difficulty in keeping the intestine out of the way on account of the great distention. The cecum was bound down in the iliac fossa, and, by passing toward the ascending colon, a small hard mass the size of a large English walnut was detected. A small transversal incision perpendicular to that in the median line was made in order to give more working space, and after a long and difficult dissection with the fingers the cecum and neoplasm were freed of the adhesions and brought up into the wound. The growth was an annular carcinoma of the intestine situated at the junction of the cecum and ascending colon. Search was made for enlarged lymphatic glands of the mesentery, but none could be found. At this point of the operation the patient, who had been in a very precarious condition, showed such a marked state of collapse that the time necessary to do a resection of the cecum and intestinal anastomosis could not be spared, and it was decided to make an artificial anus in the cecum with the hope that the patient might rally sufficiently to undergo resection of the cecum and part of the ascending colon in a short time. An artificial anus was made in the median line, according to the technic advocated by Mr. Cripps. The patient, however, only survived the operation a few hours.

The symptoms of carcinoma of the cecum have their importance because, by reason of the small number of cases that have been diagnosticated as such during life and have been reported, little

attention has been given them in the classical works on general or special surgery. The commencement of the disease is usually remarkable by its latentcy, but always comes to an end as soon as the growth has developed sufficiently to be made out by palpation, and at this time the period of full development has been reached. The symptoms which first draw the physician's attention to the cecum do not always follow in the same order, but in the order of frequency of their apparition they may be classed as follows: (1) Pain; (2) alternating diarrhea and constipation; (3) loss of flesh; (4) dyspeptic disturbances; (5) intestinal hemorrhage. Occasionally the functional symptoms are absent, and only those are met with which occur when it has arrived at its full development, and thus we find reported cases in which the tumor in the right iliac region was detected before it had given rise to any other symptom, while in one case the affection made its presence first known by the formation of a fecal fistula.

Pain is usually the first symptom complained of by the patient and in the beginning has no precise localization, but later on it becomes localized in the right side of the abdomen, more particularly in the iliac fossa, and then it will shoot down the legs into the lumbar or sacral region, or toward the umbilicus, as in our case. In the case I have here related the pain, which followed a traumatism on the abdomen, never completely disappeared after the accident, and this has been the history in several other reported cases. Kraussold relates the history of a patient who received a kick in the right iliac fossa and pain persisted for six years with slight remissions, and then disappeared completely after a spontaneous fecal fistula had formed. Pain may be produced by movement, and in one case the patient who remained in bed lying on the back complained of pain as soon as any motion was imparted to the right leg. In other cases the pain was greatly increased if the patient became constipated, and would completely disappear after the bowels had been moved, while in other cases pain was constantly present and increased during meals; I would particularly insist on this point, because this symptom was very marked in our case. At other times it has been found to occur at regular intervals and always at the same spot.

During the early part of the evolution of the disease an alternating diarrhea and constipation are nearly always present. Sometimes these alternatives follow vomiting, while at others an alternating diarrhea and constipation are finally entirely replaced by a continuous diarrhea, which will most likely be relieved by some astringent mixture containing opium; but, nevertheless, the diarrhea may become uncontrollable and even be the cause of death. In other cases constipation becomes more and more obstinate and may give rise to symptoms of intestinal obstruction. There is hardly any case recorded where sooner or later the passage of feces did become sufficiently difficult to produce accidents of severe type, but the obstruction was in most cases simply temporary, and was relieved by proper medical treatment. In other cases diarrhea alone was present, and it may exist for a long time; the liquid feces have no particular pathognomonic significance; occasionally pus and blood or pus alone may be present.

Violent intestinal colic may be added after a time to the foregoing symptoms and become most excruciatingly painful and constantly present. It is the result of violent intestinal contractions due to the obstacle which is opposed to the downward movement of the intestinal contents by the neoplasm, and it reaches its maximum of intensity when the bowel has become completely obstructed.

Some patients become thin and lose their strength at the very onset of the affection, and the loss of flesh may be very rapid. Digestive disturbances have been frequently met with during the initial period of carcinoma of the cecum. They consist principally of nausea, vomiting, anorexia and difficult digestion. The vomitus is usually mucous, but it may become bilious and contain food. Fecal vomiting will occur if symptoms of occlusion arise, but they may subside spontaneously or by an appropriate treatment. In one case fecal vomiting occurred one year before any tumor could be palpated. Vomiting has been observed when the obstruction was not very marked. In other cases the vomitus was yellow and had a fecal odor, but was not fecal in nature, while other patients complained of a fecal taste in their mouth without having fecal vomiting. Many years ago Despres pointed out that when yellow vomitus with a fecal odor took place, or when patients complained of a fecal taste, carcinoma of the intestine should be at once suspected.

Intestinal hemorrhage is not a frequent symptom in carcinoma of the cecum, but small hemorrhages may occur which color the feces black; in a few instances the hemorrhage was sufficiently severe to become serious. In one case the blood was mixed with pus.

The physical symptoms are observed when the carcinoma of the cecum has attained its full development, and they characterize the disease. By far the most important is the appearance of a tumor in the right iliac fossa. In the early stages it is movable under the abdominal wall and also over the deeper structures. The neoplasm, which in the beginning is limited to the intestine, will finally invade the pericecal cellular tissue and throw out narrow adhesions between the diseased structures and the iliac fossa, or the neoplasm may become adherent to the abdominal wall. Later on the lymphatic glands become involved and their number and size vary very greatly in different cases. After the lymphatics have become greatly involved a large tumor may be felt which may project at a point quite distant from the primary neoplasm, as, for example, at the umbilicus or in the epigastric region. The tumor will now be found to be very adherent, and it may happen that from its size it compresses the

iliac vessels so that an edema of the right lower limb will arise.

The next case is that of carcinoma of the gall-bladder with secondary deposits in the liver, and it is particularly interesting inasmuch as it is an additional proof that gall-stones are a causative factor in the etiology of carcinoma of the gall-bladder.

Case VII.—Mr. W. F., aged forty-nine years, had always been in excellent health with the exception of typhoid fever fifteen years ago. During the last seven years he had had frequent severe attacks of gall-stone colic accompanied by great pain and marked jaundice. For the last two years these attacks had become more and more frequent so that when I first saw the patient in January, 1897, he was having them on an average of every ten weeks. I attended him through three attacks of gall-stone colic as severe as I ever saw, and finally got the patient's consent to operate for their removal.

Cholecystotomy was done in September, 1897. The operation was very simple; the gall-bladder was not very much enlarged and was easily drawn up to the incision and sutured to the peritoneum. It might have been the size of a small Bartlett pear. After the gall-bladder was incised, it was found that its walls were of excessive thickness, measuring about 2½ centimeters. A small amount of bile came away through the incision in the fundus of the organ, and four large mulberry calculi, varying in size from a strawberry to a cherry were removed, as well as 25 or 30 smaller stones. Two large rubber drainage-tubes were placed in the gall-bladder and the remainder of the abdominal incision was closed. Convalescence was uninterrupted; the drains were removed at the end of ten days and the wound healed immediately, no fistula remaining, and the patient was discharged from the hospital in about four weeks.

He remained in excellent condition until May, 1898, when he came to me complaining of a fulness in the region of the gall-bladder, which interfered somewhat, as he thought, with respiration, especially when he went up-stairs or coughed, on which occasions he felt a few stinging pains. Palpation revealed a mass in the region of the gall-bladder, and the liver dulness was increased about one fingerbreadth below the border of the false ribs. In every other way the patient felt perfectly well; his bowels were regular and the stools were dark in color. His appetite was good, although his tongue was somewhat furred, and he slept well.

I made a diagnosis of carcinoma of the gall-bladder and advised immediate operation, which was done two days later. An incision carried along the external border of the rectus was made, and after exploring the abdomen it was found that the gall-bladder presented a large number of nodules over the surface, and that it was intimately adherent to the duodenum, the omentum, the abdominal wall, and the under aspect of the liver. After separating the adhesions, which was a rather delicate proceeding, it was found that the entire gall-bladder had undergone a carcinomatous transformation, and that on the border of the right lobe of the liver was a secondary deposit of the neoplasm, in circumference about the size of a 25-cent piece. Cholecystectomy was performed, the area of the liver to which the gall-bladder adhered being removed by the Paquelin thermocautery, and then we proceeded to remove that portion of the liver which had become secondarily involved. With the Paquelin a V-shaped resection of the liver was made, including the carcinomatous nodule. The piece of liver removed was triangular in shape and measured 11 by 6½ centimeters. On section it was found that the secondary carcinomatous nodule was entirely imbedded in healthy parenchyma, so that we felt sure that we had freely removed the growth. After the piece of liver had been removed, a large vein in the parenchyma of the organ began to bleed very freely and, as much blood was being lost and the hemorrhage could not be controlled by packing, a stout needle was passed through the liver parenchyma and brought out so that a ligature was passed around the bleeding vessel and tied, completely controlling the hemorrhage.

The large cavity left by the removal of the gall-bladder and the resection of the liver was packed with gauze, which was brought out at the upper angle of the abdominal incision, the remainder being closed in three layers of sutures. After this operation the patient made an uninterrupted convalescence; all the gauze packing was out by the end of a fortnight, and he was discharged well five weeks from the time of the operation. We saw the patient in August, 1900, at which time he was complaining of considerable pain in the abdomen, and was deeply jaundiced. Abdominal palpation revealed an enlarged liver, its borders reaching four fingerbreadths below the border of the ribs, and over its surface could be felt a number of nodules of carcinoma.

There is no doubt in my mind that at the present time the only proper treatment of cases of carcinoma of the gall-bladder and of the liver is cholecystectomy and resection of the diseased portion of the liver. Generally speaking, I believe that cholecystectomy as a typical operation should be confined to cases of severe inflammatory lesions and malignant tumors of the gall-bladder, which, as we all know, are most frequently carcinomatous in nature. The experiments carried out by Rose all justify the opinion that extirpation of the gall-bladder is only justifiable in cases of malignant transformation or severe inflammatory lesions, and Heddaeus says that in cases of extensive carcinomatous transformation of the gall-bladder cholecystectomy is the proper operation to select, and if the liver be also involved in the process, partial resection should be attempted.

Extirpation of the gall-bladder for carcinoma was first performed in 1887 by Bardenheuer, but the patient died shortly afterward from a cardiac embolus. Hochenegg of Vienna was the first to

successfully remove the carcinomatous gall-bladder combined with extirpation of a good-sized piece of carcinomatous liver. His patient was a woman, aged fifty-eight years, who for six months had complained of pain under the right costal border, with loss of flesh and the presence of a tumor the size of a hen's egg in the region of the gall-bladder. The growth appeared to be very hard, and, as it could be displaced by palpation, it was uncertain whether it was connected with the liver or not, and the diagnosis of carcinoma of the pylorus, or of the colon, was made, which proved to be incorrect when the abdomen was opened. It was then found that the gall-bladder was considerably enlarged and as hard as stone, and a tumor the size of a walnut was found in the edge of the liver and had infiltrated the parenchyma of the organ to about two centimeters in depth. A loop of intestine which was adherent to the gall-bladder was peeled off and then drawing the right border of the liver forward, dissection was carried out as far as the cystic duct. The latter was freed of its attachments and then cut between two ligatures with a Paquelin cautery, and the part adherent to the gall-bladder was separated from it without much hemorrhage. Then the region of the liver which was infiltrated by the secondary deposit of the neoplasm was excised by means of a curved incision, which included normal parenchyma of the organ; hemorrhage was only moderate in amount. When the wound in the liver was brought together by sutures, these tore out, so it was decided to treat the part extraperitoneally, and in order to do this iodoform-gauze tampons were fixed in place by mattress sutures, the whole being covered by an abdominal dressing. When this was changed eleven days later the liver was found to be granulating well and a perfect cure was effected in six weeks after the operation. Seven months later no recurrence had taken place.

The gall-bladder which had been removed contained 52 stones, some of them the size of a cherry. The walls of the organ had undergone a fibrocarcinomatous transformation and were about 6 millimeters thick. The piece of liver removed measured 3½ centimeters in thickness and 4½ centimeters in length; the free border showed the presence of a carcinomatous infiltration, but the section had been carried in perfectly normal parenchyma.

Von Winiwarter has recorded the case of a woman, aged fifty years, who six months previously had become suddenly attacked with pains in the epigastrium without any apparent cause; they radiated toward the right and then suddenly disappeared. After this attack the patient felt quite well for several months, although there were certain digestive disturbances from time to time. During the past five or six weeks she again complains of pains, the attacks occurring five or six times a week and generally lasting from half an hour to an hour. The patient also complained of great weakness and general debility. The feces were at no time discolored, but small gall-stones were found from time to time. By palpation no tumor could be made out, and there was no apparent increase in the size of the liver, and a diagnosis of biliary calculi, with probable carcinoma of the gall-bladder, was made.

The abdominal cavity was opened by a longitudinal incision carried along the external border of the rectus muscle. The liver was found to be normal in consistency, while the gall-bladder had reached the size and shape of a medium-sized pear. It had contracted adhesions with the surrounding intestine and was quite as hard as cartilage to the feel. These adhesions were ligated and cut and the fundus of the gall-bladder was temporarily walled off from the peritoneal cavity by strips of gauze, after which it was opened. The wall of the organ at its fundus was nearly a centimeter thick, and presented a carcinomatous transformation. Near the upper surface, which was toward the liver, the wall of the organ became thickened forming a nodule the size of a hazelnut. The gall-bladder contained but a small amount of bile, and over a dozen small, light, faceted calculi. The carcinomatous wall of the gall-bladder had become intimately connected with the parenchyma of the liver, and at the sharp border of the latter there was a whitish nodule of carcinoma the size of a walnut, set in the parenchyma of the liver. The cavity of the gall-bladder was emptied and then packed with tampons, and then silk ligatures were carried through the liver substance and tied, after which the incision was carried into the normal parenchyma of the organ with the knife of a thermocautery, and the piece was removed without hemorrhage. Sutures were then passed around the carcinomatous nodule in the liver, and a wedge-shaped piece containing the secondary deposit was excised. The cystic duct was then isolated, but the operator was obliged to go as far back as the ductus choledochus, because at this point there was felt a small nodule and it was uncertain whether or not it was a stone or a malignant deposit. A ligature was then passed beyond this nodule and the entire gall-bladder with the cystic duct and pieces of liver were removed. The pedicle was then drawn out and united to the parietal peritoneum by means of sutures. The stump contained the commencement of the ductus choledochus as well as the opening of the hepatic duct. The cavity was then packed with idodoform gauze and the remainder of the abdominal wound was closed by layers of buried suture.

The specimen showed that the wall of the gall-bladder had become thickened to about double its natural size; it was fibrous and interspersed with very hard, white nodules the size of a hazelnut while the nodule removed from the liver microscopically proved to be a secondary carcinomatous deposit.

Within two weeks after the operation a roundish growth the size of a hazelnut was noticed at the bottom of the fistula which had existed since the operation. This nodule had evidently developed from the suspicious formation which was

present on the surface of section of the ductus choledochus, and the recurrence had started and developed so rapidly that the patient died six weeks after the operation.

(To be Continued.)

CLINICAL MEMORANDA.

PREGNANCY AND TYPHOID.

By G. H. B. TERRY, M.D.,
of Wyalusing, Pennsylvania.

On October 26, 1900, Mrs. M. G., aged twenty-nine years, during the fourth month of her third pregnancy was attacked by typhoid fever. The temperature during the first week rose to 104° F., pulse 112. The symptoms then gradually abated and the patient was convalescent at the beginning of the fourth week.

On April fifth following the attack the patient gave birth to twin girls, healthy and weighing respectively six and seven pounds.

The diagnosis of typhoid was at no time in doubt, but was strengthened by the fact that a sister of the patient contracted the disease while engaged in nursing the case referred to and also by the fact that a member of another family who moved into the same house contracted the disease a few months later.

The case is interesting, showing as it does that pregnancy, even a twin pregnancy, does not confer immunity to typhoid, as was at one time taught, and that however undesirable it may be to have pregnancy exist during the disease, it does not necessarily interfere with its favorable termination.

FOREIGN BODY IN THE URETHRA.

By H. W. CLOUCHEK, M. D.,
of Ann Arbor, Michigan.

A peculiar case came under my notice in December which I thought might interest your readers, having noticed various articles in the Medical News of cases with foreign bodies in the urethra.

The history of the case, in brief, is as follows: A. D. S., male, aged seventy-two years, American, contractor, married, was admitted to hospital December 6, 1900, because of pain in the bladder and difficulty in passing urine. The patient has had heart trouble and a double hernia. The present trouble began about four years ago with trouble in holding the urine. A physician at that time sounded, found a stone in the bladder, and advised operation. This was declined by the patient. Four or five weeks ago he was unable to urinate and inserted a straw of "barn grass," about seven inches long, into the urethra in order to relieve pain. On letting go of the penis its head was drawn over the end of the straw and the patient was unable to extract it. Three days later a brick-dust material came away, then blood and pus. The discharge of pus has continued up to the present time. The urine is dark and cloudy and contains large amounts of albumin and pus. Examination shows the straw in the urethra extending up into the bladder. I have known of many articles being used as a catheter, but this is the first instance which has come under my observation in which a straw was employed for this purpose.

MEDICAL PROGRESS.

Active Principles of Digitalis.—Much uncertainty has always existed concerning the relative value of the several preparations of this drug, and especially in regard to the physiological action of the various active principles which have been so poorly isolated. The rules governing the selection, gathering, preservation and preparation of this drug are so lax that certainty of action cannot be expected. L. L. Solomon (*N. Y. Med. Jour.*, Feb. 9, 1901) enumerates the glucosides as six forms, of digitalin, digitoxin, digitophyllin, digitalein, digitonin and digitin. The solubilities of the several principles are not identical and, hence, the activity of a tincture, a fluid-extract and an infusion are by no means the same. Digitonin, readily soluble in water, sparingly in alcohol, is a cardiac depressant, antagonizing the cardiac action of digitalin and digitoxin, but it is the most active diuretic principle and is very irritant to the stomach. Digitin is inert and very little is known of digitophyllin. Digitalin, digitalein and digitoxin are all cardiac stimulants, acting on the heart-muscle. Digitalin is unique on account of its special influence in contracting the blood-vessels, increasing the pressure and slowing the heart. Digitoxin does not raise pressure and, as has been demonstrated, dilates the renal vessels. The therapeutic value of the latter preparation when isolated is, therefore, much enhanced. Digitoxin acts quicker than digitalin, sometimes within twelve hours, is less liable to cumulative effects, and much more diuretic. The uniformity of its action and strength will make it a very valuable drug. It is administered hypodermically or by the mouth, in doses of $^1/_{250}$ to $^1/_{1000}$ of a grain. Since it is liable to be precipitated on coming in contact with the secretions, the author has found the following an admirable vehicle:

℞	Digitoxin	(gr. $^1/_{250}$)
	Chloroform	(♏ jss)
	Alcohol (90 %).....	(♏ xxiij)
	Aquæ .....q.s. ad.	(℥ ss)

Congenital Hypertrophy of Cervix Uteri.—Abram Brothers (*Am. Gyn. and Obstet. Jour.*, Jan., 1901) reports the case of a girl, seventeen years of age, who presented this rare condition. She began to menstruate at eleven and was always regular. When she was fourteen years old she noticed the womb projecting from the vulva.

She underwent an Alexander operation at one of the large hospitals, but left at the end of five weeks absolutely unrelieved. From that time, until she came into the writer's hands, she went from one doctor's office to another. Brothers found a slim, delicate, anemic child, with an expression of anguish on her face, who walked with body bent forward, evidently suffering great pain. She was feverish and complained of anorexia, vomiting, diarrhea, and pelvic pain. The cervix was eroded and protruded one inch from the vulva. There was a cystocele and also a rectocele. A thick mucopurulent discharge filled the uterine canal. The uterus was large, and on both sides of it were large, boggy masses, tender to the touch. A diagnosis of complete prolapse of the uterus, with bilateral pyosalpinx, was made and the uterus and pus tubes were removed in one mass. The girl left the hospital on the sixteenth day, and when seen six months later was still perfectly well. Measurement of the uterus showed that the distance from the fundus of the uterus to the internal os was one inch and that between the internal os and external os was two and a quarter inches. Therefore, the case was one of congenital hypertrophy of the cervix, associated with prolapse of the uterus and later complicated with bilateral pyosalpinx. Brothers thinks that the pyosalpinx was the result of the free use of sounds, etc., while the girl oscillated from one doctor's office to another, and that there was no reason to suspect a gonorrheal origin.

Intestinal Hemorrhage and Fatty Heart.—A patient, fifty-eight years of age, usually very well, was operated on by C. Phelps (*N. Y. Med. Jour.*, Feb. 9, 1901) for an umbilical hernia. During the anesthetic he was very cyanotic and his breathing was irregular. He reacted well, but on the third day his pulse and temperature were very high and on the fourth day signs of internal hemorrhage and collapse appeared. Much blood was passed from the bowels and some was vomited. Autopsy showed a healthy wound and peritoneum, a moderate cirrhosis and a very fatty heart. The muscular walls of the right ventricle were not much thicker than paper. The additional strain of the anesthetic and operation is supposed to have overburdened a weakened heart and induced sufficient congestion to result in hemorrhage from the intestinal and stomach mucous membranes.

Retropharyngeal Abscess in Adults.—This condition rarely occurs after the age of four. Bokay classifies retropharyngeal abscesses as follows: (1) Idiopathic abscesses; (2) secondary abscesses from disease of the cervical vertebræ or from irrigation of pus from a superficial cervical adenitis; (3) septic abscesses; (4) abscesses from trauma. J. L. Goodale (*Boston Med. and Surg. Jour.*, Jan 31, 1901) reports a case of retropharyngeal abscess of special interest, because of the age of the patient and because of the demonstration of tubercle bacilli in the pus. The patient was a youth, eighteen years of age, who, though feeling perfectly well, complained of a swelling in the back of his throat which had been developing for four weeks. Examination showed a bulging forward of the whole posterior pharyngeal wall, due to the fluctuant swelling extending downward from the level of the soft palate. The mucous membrane over the swelling appeared normal. A free incision was made and about four ounces of pus evacuated. A guinea-pig, inoculated with the pus, was killed seven weeks later and showed all the characteristic lesion of tuberculosis. This case seems unquestionably one of tuberculous retropharyngeal lymphadenitis, ending in suppuration. The writer says that he has been unable to find in literature any report of a case of tuberculous retropharyngeal lymphadenitis in the absence of caries of the spine, such as the case he now reports.

Infantile Scurvy.—This condition is, in most instances, one of the easiest of all the diseases of infancy to diagnose, as well as to treat. In some cases it is more difficult to recognize, generally because at first the symptoms simulate other affections, particularly rheumatism. Crozer Griffith (*Phila. Med. Jour.*, Feb. 2, 1901) reports in detail sixteen cases, most of which presented symptoms simulating rheumatism. In some of these cases a diagnosis of rheumatism had been made by the attending physician. Pains in the arms or legs were an early symptom in these cases, followed by a swelling and redness, and also bleeding of the gums. The children also lost flesh and became peevish and fretful, crying a good deal. The pains in the legs were often of an intermittent character, sometimes disappearing for days. In some of the cases the diagnosis was rather difficult, being established only by treatment. In one case hematuria was the sole symptom of scurvy, and this disappeared completely after a few days' treatment with orange-juice. The cause of scurvy is clearly dietitic, yet no one dietetic fault can be held responsible. Most of these cases had been fed upon some commercial food, such as Horlick's Malted Milk. One of these cases promptly got well by the simple omission of the patented food from the dietary. In some cases the sterilization of milk has seemed to produce the disease. The affection of the gums is not usually the first symptom of the disease, and the disease may exist without it. This symptom is usually absent if no teeth have appeared. Pain, oftenest in the legs, is most frequently the first symptom, and this fact is the cause of so many mistakes in diagnosis. This is the reason scurvy is so often called rheumatism. The treatment of the disease is simple, and consists of a proper alteration of the diet and, even without this, the administration of fresh fruit-juice. Orange-juice, without any change of diet, brought about a prompt recovery in several of these cases. The diet should not be altered too quickly, lest this cause a fatal diarrhea or gastritis. Raw milk is to be preferred to heated milk, when it can be safely used.

Renal Insufficiency.—It is always important to ascertain the amount of solid matter excreted by diseased kidneys and also helpful in many cases of functional disturbances in elimination. J. T. Jelks (*N. Y. Med. Jour.*, Feb. 9, 1901) gives an easy method of making such a determination. The entire amount of urine passed during the twenty-four hours is collected. Take the specific gravity and multiply the last two figures by the coefficient of Häser, 2.33. This will give the number of grams in 1,000 cubic centimeters of urine, and the total amount can be easily obtained. A normal adult man should excrete from 1,000 to 1,200 grains according to his weight.

Corporeal Specific Gravity.—Although the absolute weight of the body is a valuable sign in determining the physical condition of a patient, yet it does not always reflect the true state of health, for a very heavy man need not be obese, nor need a light man be emaciated. Much more definite and valuable assistance can be had from the determination of the specific gravity. H. Stern (*Med. Rec.*, Feb. 9, 1901), after considerable experience, suggests that the simplest method of ascertaining this point is by the Archimedean principle by which the density is obtained by dividing the absolute weight of the body by the loss of weight which it sustains when suspended in water. He believes that if the specific gravity is below 1,063 or above 1,073, unsoundness of the organism is denoted. Low density means satiation with water or preponderance of adipose; the high figure means disturbed metabolism, general atropic state, or senility. There is also a greater predisposition to infectious diseases when the density is low, and increased susceptibility to eliminative disorders when it is high. Strength and endurance are deficient among those at either extreme, and the duration of life depends so much upon corporeal density that this physical sign should become a valuable one to life-insurance examiners.

Amœbic Abscess of the Liver.—Four cases of this disease are reported by C. R. Darnall of the U. S. Army Hospital-ship "Relief" (*N. Y. Med. Jour.*, Feb. 9, 1901), two being fatal. Amœbæ coli were found in the pus of all cases. Dysentery was present in only two. Pain in the right shoulder and right hypochondrium, tenderness and moderate fever were present in all. There were no chills, and sweating was moderate in only two patients. Emaciation was extreme and moderate leucocytosis characterized all. The appetite continued excellent and there was no nausea or vomiting in any patient.

Obliteration of Right Ureter by a Calcified Fibroid.—Maurice H. Richardson (*Boston Med. and Surg. Jour.*, Jan. 24, 1901) reports the case of a woman, fifty-eight years of age, which illustrates the dangers of leaving an old fibroid unmolested. The patient had always been well until ten years ago when she noticed in the right lower abdomen a tumor, which gradually increased in size. She had had two children and had always menstruated regularly until the menopause, which occurred when she was forty-five years of age. At times she complained of more or less pain from this tumor. She began to have frequent and painful micturition about three years ago, and at times she was unable to hold her water. The urine was cloudy and the odor became quite foul. There was loss of weight and appetite, and the bowels were constipated. On examination a large fluctuating tumor of the lower abdomen was found. On exposure of the tumor it proved to be a fibroid of the uterus, upon which was a large cyst. The tumor was either a uterine fibroid closely connected with a cyst of the broad ligament, or a fibrocyst of the uterus, and was deeply attached. The deeper portions of the tumor on the right side were calcified and of stony hardness. Separation of the tumor was exceedingly difficult. A clear liquid was noticed welling up from the deep parts. The source of this fluid proved to be the right ureter which had been torn transversely. This ureter apparently ended at the calcified portion of the tumor, as no distal orifice of the ureter could be found. Above the orifice the ureter was dilated and tortuous, and the pelvis of the corresponding kidney much dilated. The proximal end of this ureter was freed from the surrounding tissues, until it could be brought to the collapsed bladder. A small opening was made into the bladder, into which was thrust about half an inch of the ureter. The bladder about the ureter was then carefully sutured to the sides of the ureter with interrupted sutures of fine silk. The sigmoid flexure was also involved in the tumor, the removal of which necessitated a few stitches of silk to close the hole made in that viscus. The convalescence was uneventful and recovery complete.

Cause of Cancer.—When the parasitic theory in regard to the etiology of cancer was advanced several years ago, it was believed that much of the mystery surrounding this condition would soon be dispelled and methods of treatment much improved. The results of years of investigation have been, however, very unsatisfactory and the physician is still groping in the darkness of speculation. P. R. Cooper (*Med. Chron.*, Dec., 1900) believes that too much attention has been paid to the parasitic theory, not because it is improbable or impracticable, but because the relation between the physiological growth and the pathological overgrowth of proliferating tissue cells has been overlooked. Instead of wondering why the cells in certain parts of the body should become multiplied so fast and extend beyond their normal bounds, it should really astonish us more to see how cleverly Nature normally governs cell-proliferation, so that in the natural growth, maintenance and repair of the body, in spite of the rapid reproduction of cells, the development of each one is so controlled that it

passes through a series of differentiating stages and, finally, as a mature cell assumes its particular function. Undoubtedly, cancer cells are in some way developed from the normal growing cells of the tissue in which the tumor appears. Cohnheim believed that the fetal inclusion of embryonic cells was responsible for the later abnormal overgrowth, but this theory is unnecessary. Normally, cells of an embryonic type, possessing powers of reproduction, exist in nearly all parts of the body and the microscope reveals all the intermediate stages between this "mother cell"—"histogenic cell"—and the active adult cell. The typical cancer cells resemble very closely their embryonic prototypes, but instead of the activity of the reproductive process being governed by the needs of the body, the formation of new cells is apparently without any definite purpose or direction. The newly-formed cells are devoid of any tendency to development and the more malignant the tumor the more embryonic they remain. The cell increase goes on unchecked and healthy tissues are invaded. In simple tumors and inflammatory conditions, however, excessive production of cells occurs, but they undergo development and never transgress normal boundaries. The essential difference between the normal histogenic cell and the one which produces the cancer cells seems to be that the latter has lost the capacity for development and differentiation. This "integrating" power which is, doubtless, transmitted through the nucleus may have been faulty from the first and malignant tumors of infancy or childhood may result. Again, it may be easily exhausted by a number of extra demands such as a chronic irritation, and cell-proliferation would then result in the accumulation of embryonic or malignant daughter cells.

Membranous Colitis.—This may be primary, due to enteroptosis, bacterial fermentation, infection, lack of digestive ferments, or intestinal calculi, writes John A. Robison (*Medicine*, Jan., 1901), or secondary, due to dyspepsia, traumatism, and grave cachectic conditions, septic and infectious diseases, and cancer. The patients are usually over twenty, mostly women, small-boned, neuropathic, pale, and seldom bed-ridden. The skin is moist and is subject to eruptions, urticaria, eczema, etc. Insomnia is marked and the sleep of early morning may be disturbed by frequent movements of the bowels. The tongue is dry, thickly coated, the gums spongy, the breath foul, and nausea without vomiting is frequent. The stools are thin, watery, sometimes bran-like, foamy, and at times large quantities of mucus, or membranous shreds are present. Tenderness along colon, cramps relieved by heat, but not by pressure, and rectal tenesmus are common. The urine is scanty, high-colored, containing indol. Renal insufficiency is marked. The act of defecation is often painful, and may be accompanied by griping pains, prolapse of the bowel and the passage of blood and mucus. In most cases the diet should be nourishing, well cooked, and tempting. A flannel abdominal bandage should be worn. The patient should be free from care, and take light exercise in the open air. If the kidneys are not acting, give saline diuretics, alkaline waters, hot-air baths, etc. Great relief may be obtained from rectal flushings with warm water, one-per-cent. boric acid or salt solution, or 1-to-2000 silver nitrate. The author values rectal injections of methylene blue, one grain to a quart of water. The antiseptics useful for the bowel are bismuth salicylate, salol, betanaphtol, thymol, benzoic acid, menthol, guaiacal carbonate, and creosote.

THERAPEUTIC HINTS.

Lateral Curvature of Spine.—Direct general muscular exercises alone, writes Chisolm Williams, do harm in most cases, so treatment is directed to (1) the general condition; improved by fresh air and food, and as a rule fresh clothing made to allow chest development; also hypophosphites, cod-liver oil, and bland preparations of iron; (2) getting the spine straighter by manual and mechanical pressure, Barwell's rachilysis, Barwell's lateral sling, Volkmann's sloping seat, and weight pressure; (3) keeping the improved position by a Chance adaptable metal splint; (4) special exercises for each weak muscle or group of muscles until the spine is straight, then general exercises to keep it so; (5) massage, galvanism, and rubber exercisers. Under the age of five years a leather or gutta-percha splint, suitably padded, is sufficient to overcome the curve.—*Pediatrics.*

Massage of the Stomach.—According to Gustaf Norström, on account of the deep situation of the stomach and the slight resistance of the deep plane on which it rests, only a limited portion of the viscus can be reached in dorsal decubitus. For dilated stomach the author kneads at first from left to right with patient on back, the knees bent and head raised. After a few minutes he has patient lie on right side, and petrissage is performed with both hands alternately, from pylorus toward cardia. Gentleness is necessary during the séance. The sittings should last about fifteen minutes for stomach alone, and as much more time for the intestine, if there is constipation. They should begin two or three hours after a meal. The benefit most often shows first by a returning appetite, then by the disappearance of the rumblings, eructations, gastric pains, headache, vertigo, etc. At the beginning of treatment the diet must be light and limited in quantity. Besides dilatation of the stomach, massage is of benefit in chronic gastritis, dyspepsia, essential gastralgia, gastralgia due to neurasthenia or anæmia, pyloric cramp, etc., but it may do harm in ulcers or tumors of the pylorus.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, FEBRUARY 16, 1901.

BELLEVUE, THE GRAND JURY AND THE MEDICAL BOARD.

To lay blame, and plenty of it, on Bellevue and everybody connected with it, is at present the function of the reform party and the privilege of the newspaper man. We do not withhold blame, having freely expressed ourselves in the columns of the Medical News on the deplorable mismanagement of the city's hospital; but we do discriminate in the matter of laying it on.

Possibly the Grand Jury, in its laudable and efficacious words of censure, were more anxious that the facts should be brought to light, than careful on whom they put the responsibility for the condition of affairs.

The Grand Jury holds the Medical Board directly responsible for the administration of Bellevue. This unfair implication shows utter lack of knowledge of the real method of Bellevue's management. It is because the Medical Board has had no authority, without the approval of the Commissioner, that the hospital has been so mismanaged. The very abuses which the Grand Jury lays at the door of the Medical Board have been repeatedly presented to the Commissioner in reports by the Medical Board, and have been received with delayed attention.

The Commissioner has replied that there was not money enough to carry out the suggested reforms. Now that the city's attention has been aroused, lack of funds cannot longer be made an excuse.

The Grand Jury's presentment has at least had the effect of making the Commissioner agree with the Medical Board that there are abuses to reform; and has outlined the deplorable state of affairs which is only too familiar to every physician who has ever served on the staff or board of Bellevue.

The reception office is utterly inadequate to the demands made upon it. The sober, the intoxicated, the very sick and the fatally injured of both sexes must be received in a room that is too small and by physicians who must not only examine and distribute the patients, but do the clerical work of admission as well. The Medical Board ask for a suitable room, and a clerical assistant to take histories.

The Insane Pavilion, from which the first scandals issued, falls between two stools in its management. The attending physicians are paid by the city, and are not under the control of the Medical Board, and the staff physicians, who are held responsible, have had no training in the treatment of the insane. It is asked that there be a competent, well-qualified physician with a suitable salary who would devote his time exclusively to their care, and an assistant resident physician, so that the Insane Pavilion would never be without some expert physician directly responsible for its management. The nursing service of the male ward of the Pavilion should be in the charge of a carefully-selected supervising graduate nurse, assisted by trained attendants, and there should be separate wards for alcoholics and epileptics.

The dispensary is described by the Medical Board as being in a "state of vicious decay," and needs a paid superintendent who will see that the appointees attend to their duties regularly, and that the pilfering of medicines, bandages, and instruments be made to cease.

The accommodations for the paid help are miserable and dirty, and for the nurses and resident staff they are wholly insufficient. The attitude hitherto toward this state of affairs has been that reform needs money, and, the money not being forthcoming, the abuses must be considered as non-existing. Now that everybody, Commissioner, Medical Board, and staff frankly and freely admit them, the question remains, Will the

city give the money and reform the management?

It is a disgrace to New York to think that Bellevue has such a low *per capita* allowance, compared with that of any private hospital in the city. The ratio is $1.21 per day against an average of $1.98 for each patient in other hospitals. The Medical Board say on this subject: "Decent service requires fair pay and decent accommodations. To which end we earnestly recommend that the main hospital building be replaced by a modern and commodious structure, and that the *per capita* allowance for conducting it be increased to a figure approximately that under which other hospitals live."

As Bellevue cares for more patients during the year than all the large private hospitals in the city combined, it is most important that, if its funds be increased, they should be properly managed; and we can but reiterate what we have said very emphatically in a previous issue of the Medical News, that we hope the Charity Commission reform will be carried through and the management of Bellevue be vested in a Board of unsalaried trustees, as outlined by the Charter Revision Committee.

DISINFECTION OF THE URINE IN TYPHOID FEVER.

Although it has been known for some time that the bacillus typhosus may be present in the urine of typhoid fever cases, it is only very recently that the frequency of its occurrence here has been appreciated by investigators. As yet, this knowledge can scarcely be said to be universal in the medical profession. Judging from the bacteriological observations of Blumer, Wright, Besson, and Petruschky, upon the urines in typhoid fever, but more particularly upon the more comprehensive and recent work of Horton Smith, Richardson, and Gwyn, it is probable that in at least 30 per cent. or more of the cases typhoid bacilli are present in some stage of the disease; some estimate their presence as high as 50 per cent.

In most of the cases the bacilli appear in the urine generally toward the second or third week of the disease and soon disappear; but evidence seems to show that in only about ten per cent. of the cases do they persist throughout convalescence. In many cases they have already been shown to be present in the urine for periods of months; indeed, in one case reported by Houston the typhoid bacilli had existed in the urine for several years. Ordinarily they are present in pure culture and often in great numbers; despite this there may not be any change in the appearance, or composition of the urine, nor need there necessarily be any appreciable lesion in the kidneys or elsewhere in the urogenital tract. Sometimes, however, signs of cystitis or renal implication are noticeable.

Realizing the possibilities of spreading the disease through this source, the Board of Health of New York City has had circulars printed calling attention to the importance of proper disinfection of the urine in typhoid fever. The disinfection of the urine should be continued at least until health is completely restored. Almost any of the standard germicidal solutions may be employed for disinfection, carbolic-acid or bichloride-of-mercury solution will be found safest. Urine to which has been added one-third of its volume of a one-to-twenty solution of carbolic acid is thoroughly disinfected in a few minutes.

THE STATE BOARD OF CHARITIES.

The bill to abolish the State Board of Charities, and substitute a Commission of three persons to perform their duties virtually means abolishing anything like regular inspection of the charitable institutions of the State which are supported in whole or in part by public funds. Economy is a very laudable virtue, but it is a short-sighted economy that substitutes a political office for an old, well-ordered and proved system. As the *New York Evening Post* says in commenting on the proposed bill, "The members of the State Board of Charities and their employées acquire knowledge with each visitation. They accumulate their experience and record it. As they serve without salaries, and are themselves tax-payers, they have every motive to insist upon good and economical service. The last thing that the average politician thinks of is the saving of money for the State. If the Board of Charities is abolished it is almost certain that more will be spent in the State's charitable institutions than now, and that the inmates will get less value for it."

The problem before the State is not merely how to board and lodge at a minimum cost, the 60,000 bodies that are either socially defective or helplessly dependent; but how to order, discipline and repress them to their mutual advantage and the good of the State.

The State of Maine has tried to save expense

by refusing to create a State Board of Charities, and each town has provided for its paupers as it has seen fit. The happy thought of marrying female paupers to male paupers in other towns resulted in the union of two half-witted individuals. But when the bridegroom brought his wife from her almshouse to his, the one town sued the other for fraud, and it is said that the costs of the litigation have been "enough to take care of all the paupers and keep the town roads in good condition besides." We do not desire to imitate the example of Maine; nor do we desire to have our pauper bills miraculously increasing for lack of efficient inspection, and lack there will surely be if the present bill goes through.

THE SMALLPOX SITUATION.

LAST year about this time there was considerable discussion in medical circles because of the number of cases of smallpox in the United States. It was said that to avoid a serious epidemic great care and watchfulness would be needed. At the present time we have more than three times as much smallpox in this country than we had at the same time last year.

During the four weeks from December 29, 1899, to January 26, 1900, 1,064 cases of smallpox were reported to the Surgeon-General of the United States Marine Hospital Service. During the four weeks from December 28, 1900, to January 25, 1901, 3,212 cases have been reported.

The increase of the disease affects nearly every State in the Union. Only Louisiana and Tennessee have a notably smaller number of cases of the disease than last year. Many States and Territories are suffering from serious epidemics of smallpox. In Nebraska, 464 cases are reported as compared with 6 cases during the corresponding period of last year. In Oklahoma there are 401 cases reported where there were but 55 last year. Minnesota reports 362 cases; Kansas, 280; Ohio, 225; Virginia, 206; Utah, 192; Texas, 125. New York State reports 60 cases, while during the corresponding period of last year there were but 2 cases.

The reasons for this increase of smallpox are not difficult to find. Freedom from serious epidemics of the disease for nearly 20 years has begotten a false sense of security as to the danger it involves. Gradually the persuasion has gained ground that, under the improved sanitary conditions of our modern life, smallpox is no longer the dangerous contagious disease that it used to be. The necessity for vaccination has been denied by many. Revaccination has been very generally neglected. As Professor Osler has said in a recent review of the Medicine of the Nineteenth Century, "The difficulty (the unfailing recurrence of smallpox in this country) is due to the constant presence of an unvaccinated remnant by which the disease is kept alive. Besides this, too, the protective power of the inoculated cowpox is not a fixed and constant quantity. The protection may be for life or it may last only for a year or two."

The neglect of revaccination is the cause of the present situation. From all over the country come reports that the cases of smallpox occurring at the present time are many of them atypical. They are milder and begin insidiously without certain of the characteristic symptoms of genuine smallpox It is only from a series of cases and from fully-developed cases that the diagnosis of the disease becomes assured. These anomalous types of smallpox are due to the incomplete protective power of old vaccinations. A sufficient degree of immunity remains to modify the virulence of the smallpox, but not to prevent its occurrence. Smallpox is eminently a disease of the winter. This year our wintry weather has been very much delayed. That we shall have considerable cold weather, some of it for continuous periods of good length, seems certain and it is at such times that smallpox spreads with special epidemic virulence. Last year during the six months from January to July, 1900, there were over 14,000 cases of smallpox in this country. Thus far there have been three times as many cases as during the corresponding period of last year. If this same proportion should continue there will be over 40,000 cases in the first six months of 1901. It is not probable that the ratio of increase of the disease will thus continue, for already the people of the country have been aroused to some sense of the danger. Vaccination and revaccination have been taken up with a proper confidence as to their protective influence. There are still parts of the country, however, where neglect of these precious precautions is still the rule. In such places it is the plain duty of the medical profession to call the attention of communities to the dangers that threaten them and to which they are exposing others. For when smallpox becomes epidemic it takes on renewed virulence that enables it to attack even those who were before proof against its attacks.

As Professor Osler says, "Efficiently vaccinated persons may be exposed with impunity to smallpox. To be efficient, vaccination must be carried

out systematically and, if all the inhabitants of this country were revaccinated at intervals, smallpox would disappear as it has from the German army, and the necessity for vaccination would cease." Professor Osler is not as those who talk knowing not. His experience with smallpox in Montreal gives his words all the authority of an expert on the subject. Those who from the depths of their ignorance and prejudice are discouraging the practice of vaccination are almost criminal in the possible harm they may do and under present circumstances are actually accomplishing. Nothing but an almost universal recurrence to vaccination and revaccination will save this country from a serious and extremely costly epidemic of smallpox during the coming cold weather.

Let the medical profession at least do its duty by timely advice in the matter. There is nothing at the present moment that is more worthy of strenuous effort and careful attention.

ECHOES AND NEWS.

NEW YORK.

Harlem Hospital Appointments.—Dr. John J. McGrath has been appointed to the position of attending surgeon to the Harlem Hospital.

In Honor of Dr. Green.—The New York Academy of Medicine last week honored the memory of Dr. Horace Green, the celebrated specialist on laryngology. A life-size marble bust, which was made in Italy, was unveiled at the Academy last Thursday week. The bust is a gift to the Academy of Medicine from Dr. Green's widow and his son, George Walton Green.

German Hospital.—The thirty-first annual report of the Board of Trustees of the German Hospital and Dispensary of this city, which has just been made public, describes in detail the work that has been done during the year 1900 toward the erection of an annex to the hospital, at Seventy-seventh Street and Park Avenue. This annex is now in course of construction. It will accommodate seventy patients, and, according to the estimates given in the report, will cost $180,000. It is expected that the building will be completed next June.

New York Academy of Medicine.—At the Tuesday, February 19th, meeting of the Section on Medicine, there will be a Symposium on Pleurisy. The following papers will be read: "Cytodiagnosis; Its Applicability to Pleurisy," J. J. Walsh, M.D.; "The Bacteriology of Acute and Chronic Pleurisy," by Alexander Lambert, M.D.; "The Treatment of Pleurisy with a Consideration of Early and Late Tapping," by C. E. Nammack, M.D.; "The Use of Methylene Blue Injections in Pleurisy with Effusion," by C. H. Lewis, M.D.; "The Routine Treatment of Pleurisy at Mt. Sinai Hospital," by Julius A. Becker, M.D. General Discussion of the papers by Drs. I. Adler, M. Manges, H. Lilienthal, S. S. Burt, and others.

Thursday, February 21st, Dr. A. J. Lartigau will read a paper "On the Rôle of the Colon Bacillus in Human Affections," to be discussed by Drs. Biggs, Parks, and others.

East Hampton's Typhoid.—The typhoid outbreak at East Hampton, L. I., last summer has been investigated for the State Board of Health by Professor Landreth of Union College. He finds that the cause was the proximity of Camp Wikoff. The first results in the village of the intercourse, he says, were numerous cases of tropical dysentery during the fall of 1898. Later in the year there were a few typhoid cases, and in 1900 several other cases occurred within 600 feet of the site of one of the hospitals where several soldiers were sick with typhoid during the summer of 1898. The report says there is little doubt that typhoid became established at East Hampton by soil implantation, and that it was disseminated either through the agency of percolation or through the air. Professor Landreth says that unless vigorous sanitary measures are taken there is a prospect of the disease developing into an epidemic from the existing centers during the coming season.

New Hospital for Red Cross.—The New York Red Cross will erect a hospital and training school on a plot of four lots in Central Park West, 24 feet south of One Hundredth Street, which has just been bought by the Society for $100,000. The plans, drawn by Woodruff Leeming, provide for a key-shaped building, with the longer elevation fronting the Park, and estimated to cost $60,000. The hospital is to be six stories in height and to contain 100 beds, including one reserved for each nation represented in the Red Cross. The training school for nurses is to be four stories high. The building will be of steel construction, fire-proof, and will have electric elevators and every modern hospital appliance. The New York Red Cross, whose home now is at 259 West Ninety-third Street, was organized in 1894. Its officers are: William T. Wardwell, President and Treasurer; Mrs. George F. Shrady, Vice-President; Thos. A. McNicholl, Secretary; Mrs. Bettina A. Hopker-Lesser, Sister-in-Chief; Dr. A. Monae Lesser, Executive Surgeon, and Francis Barker, President of the Managing Sisters.

Bell Bill Amendment.—The amendments of the Bell Bill have been agreed upon at a meeting of the Legislative Committees of the New York State Medical Society, the New York State Medical Association, the New York County Medical Association, with Assemblyman Bell. The Bell Bill made it a misdemeanor for any person to recommend or advise any person to take any medicine or undergo any kind of regimen or treatment whatsoever; the Bill was designed to reach

the Christian Scientists, but the New York State Medical Association opposed it on the ground that "in its original form it would have made the citizen liable under the law for recommending any mineral water or prescribing a hot-water bath or any simple remedy." Dr. Harris said that the great objection lay with the definition of what constitutes a practitioner of medicine. The amendment now reads: "The construction of this article is that any person shall be regarded as practising medicine within the meaning of this act who shall give treatment to any other person by the use of any remedy, agent, or method whatsoever, whether with or without the use of any medicine or instruments, or other appliances for the relief or cure of any wound or fracture, bodily injury or infirmity, physical or mental disease."

Report of Lunacy Commission.—In its annual report, just submitted to the Legislature, the State Commissioner in Lunacy says there were admitted to the State hospitals last year 4,795 new cases of insanity, a marked increase as compared with 4,201 the preceding year. The net increase, however, at the close of the year was but 714. There were 1,029 patients discharged recovered during the year and 900 discharged sufficiently improved to enable them to return to their homes and to engage in regular employment. A gross reduction of $297,171 was made in the cost of maintenance of the 22,000 insane supported during the year, the *per capita* rate having fallen from $3.43 to $3.18 per week. The amount spent for new buildings and extraordinary improvements last year was $662,948, as against $1,126,043 for the preceding year. There was collected during the year from paying patients $210,851. There was expended for salaries and wages of employees in the State hospitals $1,442,001. The total value of real estate of State hospital buildings is $21,600,000, while the personal property is valued at $1,670,000. The balance of the million-dollar appropriation for new buildings and extraordinary improvements, granted by the Legislature in 1900, will be required to finish the new colony at Central Islip, including accessory buildings.

PHILADELPHIA.

The Protection of Water Supplies.—The Association of Health Authorities and Sanitarians of Pennsylvania at their annual meeting asked of the Legislature the passage of a bill embodying the following points: (1) Providing that constables shall be health wardens and receive $10 for each conviction of pollution of streams; (2) making it compulsory for school boards to organize local boards of health; (3) appropriating $15,000 to the State Board of Health for the supervision of water supplies and the protection of public streams against pollution.

Board of Health and Anti-Vaccination Bill.—The Board of Health met in special session February 11th to protest against the passage of the Anti-Vaccination Bill now before the Legislature. Many prominent physicians were present to declare their opposition to the repeal of the present law. The following action was taken: "*Resolved*, That the Board of Health of Philadelphia earnestly protests against the repeal of Section 12 of the act adopted by the Legislature of Pennsylvania, June 18, 1895, which requires that the fact of successful vaccination or a previous attack of smallpox, as the case may be, must be duly certified before a child is admitted to any school in the State."

Camps for Consumptives.—Dr. J. T. Rothrock, State Forestry Commissioner, has outlined plans and secured subscriptions for the establishment of camps for consumptives on State reservations. The first camp will probably be opened in Clinton County, which has an elevation of 2,000 feet above the sea-level. Large A-tents will be erected with permanent foundations. The tents will have heavy wooden floors, and a covered platform, on which the occupants may take exercise during rainy weather, will extend in front of each row of tents. Patients will be furnished with shelter free of charge, but will have to make their own cooking arrangements. The intended ultimate result of these plans, which will soon be presented to the county medical societies of the State, is the establishment of consumptive camps on every healthy forest reservation in the Commonwealth.

College of Physicians.—The meeting of February 6th was opened by Dr. J. Chalmers Da Costa with an eloquent address in memorial of the late Sir James Paget, who was an honorary member of the College. Drs. J. F. Schamberg and J. F. Wallis exhibited wax models illustrating various cutaneous diseases. Dr. B. Alexander Randall read notes on fifty cases of otitic extradural abscess. Dr. John B. Roberts exhibited a cast and skiagraphs of Smith's fracture of the radius and Bennett's fracture of the metacarpal bone of the thumb. These specimens were from Dublin and will be deposited in the Mütter Museum. Dr. H. R. Wharton reported for himself and Dr. J. H. Musser the history of a case of perforating ulcer of the stomach, with recovery following operation six hours after perforation. The perforation was closed by infolding it, the abdominal cavity irrigated with six gallons of hot salt solution, and two glass drainage-tubes inserted, one reaching to the pelvis. Dr. Wharton believes irrigation and drainage of the pelvis to be two important points in the treatment. If the pelvis cannot be reached by a tube a counter-opening should be made.

Organotherapy in Gynecology.—A spirited discussion of this subject, based on a paper read by Dr. Wilmer Krusen, was held recently at the Obstetrical Society. The paper referred to uterine, mammary, parotid, thyroid, and ovarian extracts. Thyroid has been most thoroughly tried by various observers and is the most efficient. For the past three years Dr. Krusen has been prescribing ovarian extract in three classes of cases, *viz.*, (1) amenorrhea and dysmenorrhea; (2) symptoms fol-

lowing the removal of the uterine appendages: (3) disturbances accompanying the natural menopause. No favorable influence has been noticed in the first class of cases. The best results are obtained in the second class, the congestive and nervous symptoms being distinctly ameliorated in some cases. He concludes that no definite and exact reliance can be placed on the remedy, its use being disappointing in many cases, though an occasional good result incites to its renewed use. Dr. H. A. Hare discussed organotherapy from a theoretical point of view. He believes that to form definite conclusions regarding the value of mammary-gland extract there must be a knowledge of the physiological or sexual condition of the animal from which it was obtained. Many of the present contradictory reports of its efficacy may be due to a lack of such knowledge. Again, the physiology of minute metabolism is not known. This may be different in different individuals and similar conditions or symptoms may arise from different causes in each. For this reason, also, the use of organic extracts will give conflicting results. A third point is the fact that the reporting of such gratifying results by some observers rather militates against a favorable impression of these remedies. This statement is made because of the well-known fact that from time to time enthusiasts report remarkable results from the use of certain drugs which the profession at large find of no particular value whatever in the class of cases specified. The use of parotid-gland extract in ovarian disease is not known to have a rational basis. The involvement of the ovaries in some cases of mumps may mean, not a physiologic connection, but a bacteriologic similarity between the organs at fault. The connection between the ovaries and the mammary glands is possibly only a reflex one. For these reasons organotherapy cannot be employed in a rational way until symptoms can be separated and their cause more definitely located in individual cases. Dr. W. W. Russell of Johns Hopkins University stated that organotherapy had proven practically valueless in his experience. The local use of suprarenal extract gave gratifying results in a case of hemorrhage from the kidney which had for nine months been treated unsuccessfully. Through a renal catheter, one-half ounce of a 10-per-cent. solution was injected into the kidney. This was done three months ago and there has been no hemorrhage since. Dr. E. E. Montgomery finds thyroid extract of service in women who have rather rapidly become obese, a diminution in flesh often being followed by a recurrence of pregnancy. This remedy has a certain value in the irregular bleeding of women who are near the climacteric. It also exerts a favorable influence on malignant disease by modifying the pain. Dr. J. G. Clark has for three or four months systematically used extract of parotid gland in cases of dysmenorrhea, with thus far not the slightest result. Dr. John C. Da Costa obtains rather uniformly-favorable results from the use of thyroid extract in patients with uterine fibroids who refuse operative treatment. When this substance is given in combination with nux vomica the fibroids often decrease in size, temporarily at least, and in some instances hemorrhage ceases.

CHICAGO

Gifts to Wesley Hospital.—Dr. R. D. Sheppard of Northwestern University has received donations to Wesley Hospital, one of $5,000 and one of $1,000. The names of the donors will be announced when the dedicatory exercises of the additions to the old hospital are held in May.

Decline of Smallpox.—The situation at present in regard to smallpox is reassuring, inasmuch as no new case has been detected during the first four days of this week. The record of no case among the recently-vaccinated is still unbroken, and this lesson is causing a resort to vaccination which is the best assurance against any serious epidemic spread of the malady.

Electrocution for Criminals in Illinois.—A bill to make electrocution the legal method of execution in Illinois was introduced into the Legislature recently by Representative D. E. Sullivan of Chicago. If the bill becomes a law, the death penalty will be administered in the Joliet Penitentiary and the warden or such assistant as he may designate to officiate will receive $50 for ending each human life. The method of death is thus specified: "When a defendant is sentenced to the punishment of death, the mode of executing the sentence must in every case be by causing to pass through the body of the convict a current of electricity of sufficient intensity to cause death, and the application of such current must be continued until such convict is dead." Should the bill become a law it will apply only to murderers whose crimes are committed after its passage. It is believed that this method of executing criminals in Illinois will not meet with favor among intelligent students of criminology. If the State is to continue to inflict the death penalty for the commission of certain crimes, it should adhere to the rope and the scaffold as the most effective and impressive reminder of the terrible retribution that follows the taking of human life. Hanging as a death penalty was instituted for the purpose of impressing the public mind with the horror and disgrace of crime. Nothing could be more revolting or shocking to public sensibility than the hanging of a man by the neck with a rope until he is dead. It has a traditional terror for criminals. It invests crime with an awful aspect, and the more odious and dreadful it can be made the better for human society.

GENERAL

Smallpox at Glasgow.—Up to the first of February there were 385 cases of smallpox in this city. This number is increasing daily. Last week, February 6th, 453 cases had been reported.

Death of Professor Von Pettenkofer.—Professor Von Pettenkofer, the well-known hygienist, who was eighty-three years old, has committed

suicide by shooting himself with a revolver. He suffered from melancholia.

Plague at Cape Town.—Nine new cases of the bubonic plague are reported here and in the suburbs. A child has died of the disease. The Government and the local authorities are taking strong measures to confine and suppress the outbreak.

Plague and Smallpox at Manila.—Three cases of plague and seven cases of smallpox were discovered in Manila last week. The appearance of these diseases causes no alarm to the Health Board, which is prepared to control their annual visitation, which is expected during the hot season.

Christian Science in Indiana.—Senator Wood introduced a bill in the State Legislature February 6th making it a felony punishable by imprisonment in the penitentiary where Christian Scientists treat cases of illness and death results. The purpose of the bill is entirely to exclude the practice of Christian Science from Indiana.

Medical Society of the Missouri Valley.—The semi-annual meeting of this Society will be held in the City of Omaha, on Thursday, March 21st. Those desiring to contribute to the programme of the spring meeting will please notify the Secretary of their intention at once, as papers will be assigned to a position in the order received.

Plague in Siberia.—The *Daily Mail* publishes the following from its St. Petersburg correspondent: "Serious reports are in circulation here regarding the outbreak of what was first called 'hunger typhus,' but is now officially admitted to be bubonic plague in the Khirghiz Steppes of Western Siberia. Many thousands have died in the districts between Semipalatinsk and Orenburg. The Government is sending large quantities of wheat to be distributed to the starving population, and is organizing traveling medical services to localize the outbreak."

Death of Dr. Hiram Christopher.—At the meeting of the St. Joseph (Mo.) Medical Society, January 22d, the following resolution was adopted: *Whereas*, it has pleased God, in His infinite wisdom, to call from our midst Dr. Hiram Christopher; therefore be it *Resolved*, That we express our heart-felt sympathy and sorrow at the loss of a most honored member of this Society, and of a most lovable confrére in the profession. *Resolved*, That we mourn, with the community, the demise of a fellow citizen of high literary attainments, deep moral sense, and public spirited disposition, and, be it further *Resolved*, That as a mark of respect to the memory of the deceased, this Society adjourn. M. F. Weymann, Jacob Geiger, Chas. Wood Fassett, Committee.

Prize Essay on the Dangers from Quackery.—The Colorado State Medical Society offers a prize of twenty-five dollars for the best essay, if deemed worthy of the prize, pointing out the dangers to public health and morals, especially to young persons, from quackery as promulgated by public advertisements. The competition is open to all. Essays must be typewritten in the English language, and submitted before May 15, 1901. Each essay must be designated by a motto; and accompanied by a sealed envelope, bearing the same motto, and enclosing the name and address of the author. The essay receiving the prize will become the property of the Society for publication. Others will be returned on application. Essays should be sent to the Literature Committee, Room 315, McPhee Building, Denver, Colorado.

Christian Scientists in Massachusetts.—Christian Scientists have succeeded in safely running the gauntlet of a good deal of legislation at the State House in years past, but this year a bill has been introduced which is aimed at them directly, as well as at clairvoyants, persons practicing magnetic healing and mind cures. The bill aims to have inserted in the present medical law (chapter 458 of 1894) a new section providing that "whoever, not being registered, shall advertise or hold himself out to the public as a healer of disease, or able to abolish disease or the symptoms of disease, or as competent to do surgery, or shall in any way treat or prescribe for the sick or injured for gain, shall be punished by a fine of not less than $100 or more than $500 for each offense, or by imprisonment in jail for three months, or both."

History of Plague on the Steamship "Friary" at Hull.—The history of the last voyage of this vessel, as given in the Marine Hospital Reports, that she cleared from Cardiff November 17th for Alexandria, Egypt, where she took on a cargo of cotton seed. She left that port December 22d, touching at Algiers December 30th, and reached Hull January 10th. January 8th a Greek sailor became ill and died just before the vessel reached port. The port sanitary officers visited the vessel and, after a careful examination of the body and from the history of the case, decided that he had died from "natural causes" and allowed the vessel to proceed to dock. It was thought at the time that the man had died from influenza. Saturday, January 12th, two sailors were ill and applied to the port sanitary officers for treatment, and they were also treated for influenza. One man died on the 13th and the second one the next day, and suspicions were aroused that the disease was not influenza. Two more sailors becoming ill were sent to the hospital and died, and Wednesday, January 16th, the vessel was taken away from dock and anchored in the stream, and all the crew confined on board or sent to hospital. Besides the two men who died in hospital, three others were ill and sent there, but they are convalescent without a positive diagnosis. So far as known, all cases of plague have died. A postmortem was held on the first death in hospital and the

diagnosis of plague confirmed. In one instance, the plague bacillus was found in the lung in almost pure culture. It would seem safe to suppose, therefore, that the five deaths from among this crew were all from plague. The symptoms in all cases were indefinite, and suggested influenza. There was fever, and general aches and pains, some cough, but very little expectoration, and not the usual pneumonic symptoms. In no instance was there any glandular enlargement. The danger from this vessel lies in the fact that she came to dock and was there for several days, and was visited by numerous people, while three of the men died on board of her. One of the physicians who had attended these cases has been ill, but a diagnosis has not been made. As regards the source of infection on board this vessel, the most probable source would seem to be Alexandria, although this port at the time of sailing of the "Friary" was supposed to be free from plague, and clean bills of health were being issued. However, the period that elapsed from the time of leaving Alexandria, December 22d, to the time of sickness of the Greek sailor, January 8th, is longer than the usual incubation period of plague. Inquiries made concerning rats showed that two dead rats had been found on board, and a cat that came on board in Alexandria became ill, but unfortunately was thrown overboard in the Humber, so no bacteriological examination was possible.

Obituary.—Dr. William H. Edsall died in Highland Falls, N. Y., last week, aged forty-nine years. He leaves a widow and daughter. He was an active member of the Knights of Honor, Knights of Pythias, Foresters and Odd Fellows. He was a prominent Democrat and has served as health officer for a number of years.

Dr. Benjamin Franklin, a native New Yorker, who for a quarter of a century practised medicine in Newark, died last week at his home, 121 Fifth Avenue. Grip caused his death. Dr. Franklin was a veteran of the Civil War, and was a prisoner for seven months at Andersonville. He also served with the Cuban patriot army in the ten-year war in Cuba. Dr. Franklin was fifty-four years of age and a graduate of the University of New York. A widow and four daughters survive him.

Dr. Samuel Clagett Busey, one of the oldest and best known physicians of Washington, died in that city, Tuesday, Feb. 11th. He was born in Montgomery County, Maryland, in 1829. He was professor of materia medica at Georgetown University for many years and was the author of 163 contributions to medical literature. He also contributed to the historical works on the District of Columbia.

Dr. Peter M. Barclay, one of the eminent physicians of the Hudson River Valley, died last week at Newburgh. He was sixty-eight years old. A widow and married daughter survive him.

Dr. Frank Bond died at his residence, 27 Schermerhorn Street, Brooklyn, last Sunday. Dr. Bond was born in Erie County, Penn., in 1827. He was left an orphan while he was a mere child. When he was thirteen years old he became a farm laborer and received very little schooling until after he was twenty. He prepared himself for a university course, and finally entered Williams College in 1850. After being graduated from Williams College in 1854 he went to Iowa with the intention of teaching school. About this time his attention was drawn to medicine, and he began a medical course of study under Dr. Sanders of Iowa City. In the winter of 1855-6 he attended lectures in this city. While attending the medical lectures Mr. Bond married. After graduation he settled in Brooklyn, where he since resided. Dr. Bond is survived by his widow, one son, and a daughter.

Dr. M. G. Cunningham, a prominent physician of Binghamton, N. Y., died there Monday, February 11th. He was forty-eight years of age.

CORRESPONDENCE

THE DUTY OF THE PHYSICIAN AND LEGISLATURE.

To the Editor of the Medical News:

Dear Sir: We have had a bill introduced in the Legislature of this State which is of vital importance to the medical profession, medical colleges and medical institutions, and to the public generally. This bill, if enacted into law, will compel every person who treats disease, regardless of the method they employ, to comply with the medical laws.

The necessity for the enactment of this bill seems very plain. Under an old decision of the Supreme Court of this State, in the case of Smith vs. Lane, it was held that unless one gave medicine he did not practise medicine. The result of this decision has been that people who have desired to evade the law have adopted some cunningly-devised name, as "osteopath," "hydropath," etc., and by refusing to give medicine have set themselves up as being competent to treat disease, and the authorities are not able to successfully prosecute them.

The present medical laws, as they are now enforced are incentives to ignorant and unscrupulous people to adopt some peculiar name or title and so avoid the necessity of the careful preparation the law says a person should have before being allowed to practise medicine. The law only places obstacles in the path of those who desire to perfect themselves so as to be able to practise intelligently.

About three years ago the osteopaths had a bill introduced in the Legislature which sought to legalize their practice, but the measure failed.

They have this year attempted the same thing and their bill, which has been introduced, is stronger and has greater backing than before. It will seek to give to people who have not perfected themselves as physicians are perfected, the right to treat any and all disease by the method known as "osteopathy." If they gain this privilege it cannot be expected that other practitioners will be content to comply with the requirements of medical colleges, when they can obtain the same standing in the community by studying at some "osteopathic college." This latter course may not give them the same standing professionally, but it will enable them to rank as well, with the community, as the person who has received a thorough medical education.

Another bill has been introduced compelling the Regents to endorse the diploma of any physician who has passed the State Board of Medical Examiners of any other State. If this applied only to States where the requirements were similar, although inferior to our own, it would be bad enough: but it goes farther and applies to all States. Should this bill become a law students can then go to some State where the requirements are almost nothing, and, having received the right to practise there, can come to New York and be allowed to practise here. This will be an unfair discrimination against the medical colleges of this State, will make a farce of our medical laws, and certainly will not be of advantage to the community.

It seems to the writer that these are matters which should interest every person, physician or otherwise, who believes in upholding the present high standard of medical requirements in the State of New York, and who has the interest of the community at heart. We trust that they may interest you, and that you will use every honorable means at your command, first, to assist in the enactment of the bill known as the Bell Bill, compelling every person who treats disease, whether with or without drugs and medicines, to comply with the medical laws; second, to assist in the defeat of the Seymour Bill which would give a legal standing to a class of incompetent practitioners known as "osteopaths"; and, third, to assist in the defeat of the Adler Bill which seeks to let down the bars so that medical men of possibly inferior education and ability may be allowed to overrun the State of New York.

The writer is engaged in what he hopes will be considered a commendable effort to retain for the medical profession of the State of New York the proud position it holds in the eyes of the world to-day, and to insist that the Legislature will continue to protect the community from incompetent medical practitioners by compelling compliance with the medical laws as a prerequisite to practice.

FRANK VAN FLEET,

Chairman of the Committee on Legislation of the Medical Society of the State of New York.

New York, February 9, 1901.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, February 2, 1901.

PLAGUE AT HULL—THE PNEUMONIC FORM MISTAKEN IN THE FIRST INSTANCE FOR INFLUENZA—FOUR DEATHS ON ONE STEAMER—CREMATION OF THE BODIES—THE CASUALTIES OF DEATHS FROM DISEASE IN THE SOUTH AFRICAN FIELD FORCE—THE FAILURE OF PHYSICAL EXAMINATION IN THE DIAGNOSIS OF PHTHISIS.

PLAGUE has made another attempt to invade Great Britain. A steamer which arrived at Hull on the 10th ult. from Alexandria on its way called at Algiers. The usual inspection of the vessel was made by the port medical officer of health and the body of a seaman who died shortly before the arrival of the vessel was removed to the mortuary. There was no sickness on board the vessel at the time of arrival, but on the 12th two of the crew became ill. The cases were diagnosed by the port medical officer and by another practitioner as influenza with lung complications. Two other members of the crew sickened on the 15th. All four have died. A bacteriological examination of the viscera of two of the patients was made by Dr. Klein and the result shows that the malady was plague. All the necessary precautions are now being taken in Hull and a medical inspector of the Local Government Board is inquiring into the matter. Altogether five deaths took place, one on the voyage, two in the docks, and two in hospital. Two of the bodies have been cremated and permission to cremate the other two is awaited. It is thought that the danger to the public is passed. The plague was of the pneumonic form.

Official tables have been issued showing the casualties and deaths from disease in the Army in South Africa. In February, 1900, the total British forces amounted to 194,000; in December to 210,000. Thus, roughly speaking, about 200,000 men were employed during the year. The total number of deaths from disease in 1900 was 7,501 which gives a rate of about 37.5 per 1,000. Those killed in battle and those who died of wounds in South Africa, 200 deaths from accident apart from battle, and 92 deaths of prisoners in captivity, when added together give a total of casualties for the year of 4,318 or a casualty death-rate of 21.6 per 1,000. If allowance is made for the invalids who died on the way home or after reaching England (whose deaths are excluded from the above list), it is probable that the death-rate from disease has been about double that from wounds. As to invaliding, 30,086 non-commissioned officers and men and 1,638 officers have been sent home as invalids, or 185 per annum per 1,000. Of the invalids sent home 5,662 were wounded, 30,243 were sick and concerning 1,081 the cause of invaliding is not specified. Of the invalids 243 have died, 1,570 have been discharged from the service as unfit, and 654 are in hospital. Comparing these returns with those of the Army in time of peace; the total death-rate of the field force during 1900

was 59 per 1,000; of the troops at home and abroad, 10.8. The four principal causes responsible for the high death-rate from disease were typhoid fever, dysentery, respiratory diseases and rheumatic fever, probably in this order of importance. Probably an annual death-rate of 10 per 1,000 was caused by typhoid fever alone. In the United Kingdom the death-rate from typhoid fever of the troops is about that of males of the same age in the civil population—0.26 per 1,000; in India from 1886 to 1895 the death-rate of the troops was 5.16; and in South Africa in time of peace, 1892 to 1896, 1.76.

In his recent Harveian Lectures on Consumption, Dr. Maguire, Physician to St. Mary's Hospital and to the Brompton Hospital for Diseases of the Chest, and one of the recognized authorities on chest disease, related the following case which has given rise to some comment on the fallibility of physical examination of the chest: A man came to the Brompton Hospital one day with unquestionable tuberculous ulceration of the larynx. He had also a cough and all the appearances and symptoms of advanced phthisis. But the most careful examination by Dr. Maguire and several medical men who were attending the clinic failed to find any but the most ambiguous physical signs in the chest. The case might have been looked upon as one of primary laryngeal tuberculosis, but Dr. Maguire was sure that it was not. On two other occasions at intervals of a fortnight the chest was further examined with the same result. But on his fourth attendance signs of cavities were found in almost every part of the thorax. The cavities could not have formed in a fortnight. Undoubtedly they were present at the first examination, but from blocking by mucus or from some other condition escaped detection. The moral of this case is twofold: First, negative results in the physical examination of the chest should not prevent a diagnosis of phthisis being made; secondly, a practitioner should not readily condemn one who has previously examined a chest and failed to find anything, although after a brief interval advanced signs of excavation are present.

TRANSACTIONS OF THE FOREIGN SOCIETIES.

French.

FOREIGN BODIES IN THE ABDOMINAL CAVITY—INTESTINAL FISTULAE—HEMOSTASIS IN THE LIVER—OVARIAN HEMORRHAGE—PYLORIC STENOSIS—TYPHOID PERFORATIONS—THE BLOOD IN CANCEROUS PATIENTS—LYMPHADENOMA AND LEUCEMIA—EARLY CEREBRAL SYPHILIS FISTULAE AND TUBERCULOSIS—TUBERCULOSIS AND THE HEART.

Chaput, at the Société de Chirurgie de Paris, December 12, 1900, related the facts of a case in in which a gauze-compress was retained in the abdominal cavity for about seven years. In 1898 he was called to treat a woman for persistent median pyostercoral fistula secondary to several laparotomies. The patient had undergone operation for two extra-uterine gestations. Hemorrhage after the second had made tamponade necessary. This was in June, 1891. An eventration occurred at the scar which made another interference necessary on account of symptoms of intestinal obstruction. It was after freeing an adherent cyst by exposing the sigmoid colon that the fistula was present. On the first of June, 1898, the operation to close this sinus was done in the midline, which revealed the tract leading down to what appeared to be a new growth of the intestine, with the peculiarity of seeming to contain soft pasty matter within a thin wall. Consequently the diagnosis of a foreign body within the gut was suggested. When the intestine was opened and the adjoining mass also, the contents were found to be a large piece of ordinary surgical gauze about fifty-two centimeters on each side. The intestinal wound was sutured, the fistula excised, the abdominal cavity drained, and the parieties closed. Recovery followed. Pilate published in 1892 a case similar to the foregoing in which the gauze was passed by the rectum. This same thing might have happened in Chaput's case, but not without causing obstruction, as the compress was so large. It might also have found its way back into the peritoneal cavity; but it could scarcely have migrated out of the fistula, because the orifice was minute. Michaux in 1892 also reported the ulceration of a piece of gauze into the intestine, which there caused such changes that the gut had to be resected. Finally Jalaguier and Mauclaire have shown that the migration of gauze in the peritoneal cavity of certain animals is possible.

Peyrot published for Pauchet (Amiens) two procedures for the successful treatment of intestinal fistulæ. In the first patient the sinus entered a firmly adherent loop of the small intestine which could not be freed. The sinus was sewn into the neighboring intestine, so as to form an anastomosis. The cure was rapid. Similarly in another patient a fistula entered the large intestine between two loops of densely adherent small gut, all too much glued together to permit of separation. The fistula was simply buried in an anastomosis between the two loops of small intestine and thus well cured.

Delbet said in the discussion that the first case could have been more easily cured by stitching the fistula against the neighboring loop. Thus adhesions would close it, without the dangers and trouble of an actual anastomosis. Tuffier said that minor measures rarely cure these fistulæ. Hence he always tears down widely the adhesions so as to expose freely the sinus for whatever treatment it may then need. Michaux said that after thus exposing the tract simple suture is the usual treatment.

Walthier communicated the results of his experiments with the method of Chaput-Prevost (Rio-de-Janeiro) for checking hemorrhage from the cut surface of the liver, employed by him in separating the xiphopagus monster recently reported to the Académie de Médecine. The pro-

cedure consists of a large loop of silk, taking in all the abdominal wall, another linked to that and embracing the liver substance, and a third through the opposite lip of the abdominal wound. Thus a chain suture and ligature combined are formed, which will stay in position and be efficacious in its hemostasis. Before attempting the separation of the monster he established the efficacy of this technic with animals. Walther adds that a compress of gauze held *in situ* by the middle loop upon the liver substance is an additional means of stopping the oozing.

Tuffier briefly reported for Le Toux (Vannes) a case of violent intra-abdominal hemorrhage from the ovary. The case was under his care within twenty-four hours and at the laparotomy he found the right ovary badly lacerated. He therefore ablated it with the tube of that side. Examination showed that the bleeding was due to the laceration of a follicular cyst, rather than of an ectopic ovarian pregnancy, as the latter are very rare if, indeed, they occur at all. Delbet said that these intraperitoneal hemorrhages do not by any means indicate ectopic gestation. He had seen one due to the rupture of a hematoma in the broad ligament originating in one of the veins of that structure.

Routier, at the meeting of December 19th, contributed notes on two cases of pyloric obstruction, submitted by Lafourcade (Bayonne). The first patient was a female, forty-three years old, long afflicted with the symptoms of the stenosis. Exploration revealed an epithelioma of the pylorus. Being unable to bring the cut ends of the stomach and duodenum together during the pylorectomy, he sewed each up and did a gastro-enterostomy supplemented by an entero-enterostomy. Recovery from the operation was complete and to-day, about three months thereafter, her general condition is very good. The other observation concerned a younger woman, apparently afflicted with a contraction due to an old ulcer. The operation here was simply anastomosis so that the gastric functions could go on. It has succeeded admirably, a large increase in the weight having occurred. Routier felt that the operator would have been safer had he done a pylorectomy here also, because no one can tell how such a constriction will develop.

Guinard, in discussing, said that during the last year he had a veritable surgical calamity in connection with gastric surgery. For three years his patient had suffered from gastric symptoms and, finally, submitted to operation. In the deep field there presented what appeared to be the stomach, with its pylorus much retracted. Therefore it was determined to do a pyloroplasty. Death supervened in two days. At the autopsy what appeared during the operation as the stomach proper was a large subcardiac dilatation and this led though a canal, eighteen centimeters long, to a prepyloric ectasis which had seemed to be the retracted pylorus itself. If he had contented himself with a gastro-enterostomy, probably the patient would have survived.

Poirier stated that on the morning of the meeting he had explored for pyloric disease and disclosed a kind of circular constriction apparently due to a localized peripyloritis. It was possible to so divide the adhesions as to restore the normal lumen. The case was mentioned merely to prove the difficulty of clinical diagnosis of such cases.

Tuffier added that diagnosis is often exceedingly difficult not only before and after, but also during operation. A year ago he operated for what appeared, clinically and in the operative field, as an ulcer, but the patient has since died of cancer. In this case he did a gastro-enterostomy. In another patient of Hayhan with anemia and with gastric symptoms, according to a careful blood examination, he explored and found an extensive growth of the posterior gastric wall. A gastrectomy was done. Recovery has since been complete. Hartmann said that one cannot too minutely repeat various clinical examinations and tests for a differentiation between cancer and ulcer. Clinical considerations, chemistry of the gastric juice and the morphology of the blood are all necessary. The blood is especially important, because in cancer its features are so distinctive. Delbet reported the successful pylorectomy for a suspicious nodule of cancerous substance with adjoining inflammation. He has recently had two deaths. In one patient a round ulcer of the duodenum near the pylorus had caused grave hematemesis, which did not cease after a gastro-enterostomy and finally exhausted the patient. The second man had pyloric stenosis. After a successful posterior gastro-enterostomy signs of the *circulus viciosus* appeared. A secondary entero-enterostomy failed to check them.

Lejars, at the meeting of December 26th, in behalf of Legueu reported two examples of intestinal perforation in the course of enteric fever. The first was in a ten-year-old boy two hours after the signs of perforation and under unfavorable systemic conditions was soon fatal. The second individual was fifteen years old and survived. The ulcers were simply sutured. With the fifteen successful cases of surgical intervention for this accident, recently collected and reported by Loison, there is a total of sixteen alive. Lejars himself had a fatality a short time ago. A student had unfortunately infected himself in the laboratory and had run an unfavorable course. The symptoms of perforation had been long present and the general condition lamentable before he was summoned and determined to take the only chance and operate. An ulcer which had eaten through the small intestine three centimeters from the cecum was found and sutured, and the general peritonitis was handled by copious, repeated hot flushings. Saline infusion braced the patient materially, and at first it was hoped that success would eventuate, but at evening he died. It is likely that

earlier operation would have cured. Rochard said he also lost three persons by being summoned too late and induced to operate. On a fourth case for Debove he operated on the diagnosis of perforation, but found none. Cure followed rapidly. Another patient with so-called appendicitis had typhoid lesions, but soon recovered after the operation. Such tend to show that interference is not fatal in enteritis.

Walther stated that within a year he was called to see a patient about twenty-four hours after the symptoms of perforation began. The signs were entirely localized and the general prostration very great. Hence he did not operate. In a few days the urine showed the establishment of an intestinovesical fistula. Spontaneous cure of this occurred in fifteen days and full recovery later. Three times during last year he has also seen patients with typhoid fever closely simulating appendicitis.

Routier has observed clinical differences between perforations during the course and at the end of a typhoid fever. The former are usually deadly; the latter are apt to be less so.

Hartmann alluded to his statement at the last meeting to the effect that in the cancerous patients the blood shows diagnostic features, especially anemia and certain forms of leucocytosis. He exposed an entirely healthy stomach recently in a woman who gave all the clinical signs of cancer of the stomach, but whose blood lacked these features. She recovered perfectly from the operation, but the issue made him wish he had heeded the condition of the blood and not interfered. Another observation concerned a gastro-enterostomy on a man for what appeared to be certainly an ulcer. The blood, however, indicated that probably a cancer was present, and this was confirmed at the laparotomy. Routier mentioned the fact, in discussing this topic, that he had recently been consulted about a woman with evidently all the typical symptoms of Reichmann's disease. His own examination was hasty, but appeared to confirm this diagnosis. On the operating table a double ovarian cyst was discovered and ablated. Such are the intricacies of diagnosis.

Vaquez, at the Société Médicale des Hopitaux de Paris, December 14th, related the features of a recent case of distinct general adenopathy of the cervical, inguinal, mediastinal and other regions, with marked leucocytosis. There were about sixty red cells to one white and the number of polynuclear neutrophile cells was augmented to about 90 per cent. The patient had been under observation for several months and the disease had very slowly increased. Meanwhile a moderate pleurisy with effusion had occurred and the transudate showed a very large quantity of the same polynuclear neutrophile cells, although otherwise clear and healthy. A similar phenomenon was extant in the saliva and urine. The liver and spleen showed no changes. Medication with arsenic and iodine availed nothing. Several injections of leucolytic serum, as prepared by Besredka, were also futile as to any influence upon either the systemic symptoms or the blood-count. The examination of one of the glands removed during life showed a most interesting atypical adenopathy, of the kind described alike by the collaborators, Bezanzon and Griffon, also by Widal and Lesné. The most important and instructive feature was the fact that the gland was filled with polynuclear neutrophile cells, seemingly identical with those circulating in the blood. There seemed to be no other cells whatever in the medulla of the nodes. In fact, the blood never contained any, but the normal elements and the ganglion showed no mycloid degeneration. The presence of an excess of the polynuclear cells in the blood, their appearance in the various body fluids, their infiltration of the lymph-node show that the case was one of common leucocytosis and make it among those of a true infectious polynucleosis and deserving of a place among the symptomatic leucocytosis and as true leucemia.

Lamy related the observation of a case of cerebral syphilis which gave the following premonitory signs. The woman was twenty-six years old and suffered from a migraine accompanied by a weakness of the upper eyelid. Very soon the migraine was transformed into a chronic cephalalgia with nocturnal exacerbations and the ptosis, at first slight and temporary, became distinct and permanent. In addition she began to show lapses of memory and general intellectual depreciation. The signs were regarded as pointing to a lesion of the base of the skull. Permanent and complete cure supervened upon the vigorous administration of antisyphilitic medication, hence the nature and site of the lesion could never be fully demonstrated. For the explanation of the iniatory and temporary symptoms it seems most rational to hypothecate a localized and temporary contraction of the arteries or some equivalent cerebral circulatory phenomenon. The point worthy of memory is that migraine with ptosis may be an early sign of a cerebral syphilitic deposit.

Barie, at the next meeting, December 21st, in elucidating the relation between ischiorectal fistulas and the early tuberculosis, said that the number of cases in which this affection precedes the pulmonary lesions is really quite rare. In his own researches he has found only five patients in whom the sinus of the rectum beyond all doubt anticipated tubercle of the lungs by a variable extended time. One of these was a woman, which is remarkable because statistics in literature show that among males 5.3 per cent. and among females only 2 per cent. show this phenomenon. In three of his five patients the ischiorectal abscess was of spontaneous origin like the rule, and in two it seemed due to trauma. The intervals after which the lung trouble began were for the first series four, three, and one and a half years and for the second series two and one and a half years.

Health Board Bill Passed.—The Senate last Thursday passed the bill abolishing the present State Board of Health and establishing a single-headed Commission, in accordance with the ideas set forth in Gov. Odell's message.

SOCIETY PROCEEDINGS

THIRD PAN-AMERICAN MEDICAL CONGRESS.

Held at Havana, Cuba, February 4-7, 1901.

GENERAL SESSION.

First Day—February 4th.

The Congress opened very brilliantly on Monday evening at the Tacon Theater with well-known representatives of Havana social and political life. About four hundred were in attendance, at least one hundred coming from the United States. The address of welcome was given by Governor General Wood. He alluded to the central position of the island of Cuba as affording a convenient meeting-place and welcomed the growing brotherhood that science welds for its votaries. He tendered to the visitors the freedom of the city.

History of the Congress.—This was the subject chosen by the Secretary-General, Dr. Coronado. It had been the intention of the authorities to hold the meeting at Caracas, but the political revolutions of Venezuela made it undesirable to do so and Havana was chosen. The presence of yellow fever almost prevented the holding of the meeting, but after many vexatious delays he was glad to welcome the visitors to Havana.

Medical History of Cuba.—The President of the Congress, Dr. Juan Santos Fernandez of Havana, chose this topic for his address. Cuba, he said, of all the Spanish dependencies was foremost in her study of the medical sciences. As early as 1546 a hospital had been erected in Cuba and, under the influence of the Dominicans, a medical faculty was added to the University which was founded in 1728. Yellow fever had always been uppermost in the minds of Cuban physicians and, late in the Eighteenth Century, Romay published quite exhaustively on the disease. He was evidently a progressive man, for he conducted a medical periodical, the first of its kind in Cuba, published many works on hygiene and was an ardent champion of vaccination, demonstrating on himself and his children the process of vaccination as early as 1804. Romay's work was taken up by Gutierrez, who founded the Havana Academy of Sciences, and was strenuous in his efforts to bring about decent sanitary conditions. At the present time the medical activity is marked; there are no less than a half a dozen periodicals, bearing on medicine and its cognate branches, and the work of others was eagerly sought and corroborated. Pasteur's work on rabies was alluded to as evidence of the wide-awake character of Cuba's pathologists and bacteriologists, for an institute for the treatment of hydrophobia was instituted in 1887, close on the heels of Pasteur's announcements. What Cuba's medical science had been in the past was but a faint glimmer of what its future would be. Freed from the yoke of the oppressor, the speaker prophesied a renaissance for Cuban medicine.

Obstetrics in Cuba.—Dr. E. Hernandez of Havana spoke of the advances made in this branch of medicine, laying particular stress on the part played by prominent Cuban physicians in the development of the specialty. He spoke of some of the causes of rigidity of the uterine cervix and of the value of symphyseotomy, in which branch Cuban medicine had much to be proud of. Special modifications of the Tarnier forceps were noted.

Second Day—February 5th.

Medicine in Cuba.—This was the opening paper of the evening session, held in the Marti Theater, by the Vice-President, Dr. G. Lopez of Havana. Cuban medicine had been hampered by the climatic conditions on the island. This made it difficult for its medical men to meet and compare notes. The successful gathering of 1890, however, had been of especial value in bringing together those from over the entire island and had given an impetus to scientific work which was making itself felt at home and abroad. Bacteriology had always had special attractions, as the infectious diseases were prevalent. Of late years much interest had been taken in the study of the medicinal plants of the island and they promised to offer an attractive field for pharmacological research.

Yellow-Fever Problems.—The most important problem for the southern countries is this one of yellow fever, said Dr. Eduardo Wilde, Minister to the United States from the Argentine Republic. Sanitation was, in his opinion, the most important factor in the problem and he urged that the Pan-American Medical Congress take upon itself the important mission of attending to this matter as an exclusive problem, if necessary. He did not seem to think that the etiologic factor was definitely known, but said that if concerted efforts were made to stamp out endemic foci, and if the various shipping ports were subjected to active and radical sanitary improvements, much could be accomplished. Money spent, even in large amounts, would give good returns, when viewed from a broad economic standpoint.

Among many other interesting remarks, he described the present high sanitary condition of that city, the great reduction in mortality and in the number of cases of contagious and infectious diseases. For the eradication of yellow fever from America, he proposed the following resolution:

To the Third Pan-American Medical Congress: First, To assemble a Congress of American International Hygiene which shall be composed of delegates from all the American governments which accept the proposed congress, whose mission shall be to establish a basis for a general international treaty, whose object shall be to formulate such laws as are necessary to eradicate yellow fever from its endemic foci or where it has developed by importation, etc.

Second, To authorize the President of the third Pan-American Congress to address the respective governments of the American countries begging their acceptance of this congress and the appointment of their respective governments.

Tuberculosis and Its Prevention.—Dr. Eduardo Liceago of Mexico had prepared a paper on this subject. The problem in Mexico was essentially the same as that everywhere else, but the theory of its contagiousness was a difficult doctrine to inculcate in the minds of the native population. For them, it seemed that large organizations, similar to the Red Cross Society, would be helpful in teaching the people of the infectiousness of the sputum, the feces, the urine and other discharges. The missions could also do good work in disseminating knowledge of the means by which early diagnosis, disinfection and isolation could be carried out. Compulsory notification was also advocated by him.

Medical Science: A Retrospect.—Dr. Luis H. Debayle, delegate from Nicaragua and Honduras, gave a brief resumé of Eighteenth Century medicine and then gave a running account of the important landmarks that have stood out in the development of medicine in the past one hundred years. Pinel, Laennec, Trousseau and Bichat were alluded to as pioneers in their respective fields, each pointing the way to more exact interpretations of morbid phenomena. The science of chemistry he believed would point the way to many truths of practical importance and would ultimately be the last resort in the analysis of the more modern methods of serumtherapy. The newer instruments of precision were also discussed by the writer in their relation to more exact diagnosis.

The author spoke with special pride of the work of Ramon y Cajal, as a Spaniard whose investigations, with those of Golgi and Källiker, have revolutionized the knowledge of the anatomy and histology of the nervous system and have made possible the interpretation of morbid nervous conditions hitherto clouded in obscurity. The discovery of Morton, and Lister's application of Pasteur's teachings have been the signal epoch-making discoveries in the surgical field. The modern science of bacteriology is but an infant in arms and the secrets of serum therapy are still unborn, but are destined probably to be among the brightest discoveries of the new century.

Third Day—February 6th.

The Secretary, Dr. Acosta, rendered his report. Among other items he gave the attendance of this and of the two previous Congresses:

First, 1893, 1,040, Washington.
Second, 1896, 440, Mexico.
Third, 1900, 375, Havana.

The next meeting of the Pan-American Medical Congress will be held in the city Buenos Ayres, Argentine Republic, in 1903.

Drs. Roland G. Curtin and Hudson Makuen of Philadelphia, Committee, drew up and read the following resolutions on the late Prof. Wm. Pepper of Philadelphia.

"It is with unfeigned sorrow that we mourn the untimely death of our honored President, Dr. William Pepper, who organized the Pan-American Medical Congress and so ably and successfully presided over the two first meetings. To his wise supervision is due much of the success of the Congress since its inception. At this time we especially feel the loss of his guiding hand and executive ability to help us in achieving still greater success. In our grief we are not alone, for many and varied enterprises are hampered by the absence of his painstaking care; among the more prominent may be mentioned the Congress of American Physicians, the University of Pennsylvania, the Commercial Museums (a great and original conception of his own), and the Archeological Museum of Philadelphia. Let his example of untiring industry and the memory of his useful life spur us on to carry out the important work planned by our beloved President, Dr. William Pepper. May the crown of glory which he richly deserved be his is the prayer of his associates of the Pan-American Medical Congress."

International Responsibilities, Sanitation and Progress.—Dr. Walter Wyman, Surgeon-General of the United States Marine Hospital Service, read this paper. If there are several specifics for various diseases such, as smallpox, plague, diphtheria, etc., why do they persist? Because sanitary application has not kept pace with sanitary knowledge. The pride of municipalities should consist in perfect sewerage, paving, light, and ventilation in its houses—slums should not exist; the death-rate in them is 50 to 150 per cent. greater than in the better parts of a city and the average length of life shortened by at least ten years. Good sanitary surroundings are the best methods to get rid of disease. Professional sanitarians should be a class of men well versed in law—the average doctor makes a poor legislator. A good lawyer would make a better health officer than the average doctor. The future sanitary legislation should be toward improving the dwellings of the poor, reclaiming slums and rookeries. There are 44,000 tenement-houses in New York and 2,000 are being added every year. He cited the great reformatory experiment being carried out in London, involving an annual expenditure of $10,000,000 and affecting 40,000 people. He advises that the health officer of a city should never be a political appointment. Municipal cleaning and sanitation are not a field for National Government. The sanitation of sea-port cities by the Federal Government is now being considered. International agreement upon the eradication of yellow fever from this hemisphere is a good idea, but it would be difficult to establish it. The city of Santiago de Cuba, formerly a pest-hole of yellow fever, has now been free from the disease for more than a year. This is a good example of what sanitation may accomplish. In Havana the average mortality

for nine previous years has been 46.71 per thousand; in 1900 it was 24.40 per thousand. Four requisites are necessary to accomplish these results: (1) Effective sanitary administration; (2) good sewerage and drainage; (3) sanitation of harbor; (4) disinfection of infected houses or their destruction.

A short address was delivered by a Mexican representative, who proposed an international congress for the suppression of alcoholism.

SECTION ON GENERAL MEDICINE.

First Day—February 4th.

Propagation of Yellow Fever.—The session was opened by Dr. Carlos A. Finlay, President of the Section, who read a paper on this subject. In 1812, he said, Dr. Colomar, describing the epidemic in Murcia, suggested the contagious character of this disease and appreciated many of the natural influences which limit the communicability of it. Dr. Barton (1853) found that a temperature below 60° F., or above 90° F. was very unfavorable to propagation and Dr. Pennell showed that a number of patients moved to an altitude of 3,000 feet in no instance communicated the disease. The steamship "Plymouth" investigation in 1880 led Dr. Bemiss to report that the poison of yellow fever "is reproduced chiefly, if not wholly, within the body of the patient, but undergoes some change after its escape from the body, which increases its toxic qualities." Dr. Finlay expressed the opinion in 1881 that three conditions were necessary to the spread of the disease: (1) A previous case of yellow fever; (2) a person susceptible to the disease; (3) "the presence of an agent entirely independent for its existence of the diseased, but which is necessary in order that the disease may be conveyed from the patient to a healthy individual." He suspected the *Culex* mosquito and experiments at once justified his suspicions. He inoculated twenty soldiers by allowing the mosquito to feed upon undoubted cases of yellow fever and within two or three days permitting it to sting one of the soldiers. In nearly every instance a mild form of the disease appeared within four or five days, and the patients subsequently remained free from contagion although they had lately arrived in the infected country and were not immune. Recently the achievements of Drs. Reed, Carroll and Agramonte, with more approved and scientifically-accurate methods, have proven that the *Culex* mosquito is undoubtedly the means of communicating this virulent disease.

Prolonged Fevers of Nicaragua.—Dr. Louis H. Debayle of Nicaragua read an interesting paper in which he went over the etiology, diagnosis and treatment of these conditions. He stated that the principal characteristics of these fevers are that they are continuous, with variable remissions from time to time; that they are not typhoid in character, and that they are prolonged for weeks and months; that they rarely present renal, nervous or cardiac complications, and that they are nearly always accompanied by persistent constipation and loss of appetite, that they are very slightly influenced by quinine and antipyretics in general; that in the blood the hematozoan of Laveran is always found in one form or another. He then went on to analyze the variations in the temperature, the character of the pulse, and the condition of the various other organs during this prolonged fever. As it is rarely accompanied by death, he had not had the opportunity to make postmortem examinations. The diagnosis was at first extremely difficult, but it was necessary to differentiate it from various prolonged fevers, typhoid, bilious remittent fever, typhomalarial fever and Malta fever. With this latter it had many points of similarity, but he did not believe that the cases he had seen could come under this category. It is true that these fevers are common in malarial regions and where typhoid is rare, but he did not believe they were cases of chronic malaria, that the presence of the Laveran organism was only evidence of a double infection. In the treatment of these fevers antipyretics are of little avail, much less so quinine, given even hypodermically or in large doses. The use of intestinal antiseptics and tonics had given him the best results. His conclusions were that this was a distinct fever, different from typhoid, bilious, remittent or other acute forms of fever. Dr. Duplan of Mexico claims to have observed the same form of fever in Tierres Callintes as described by Dr. Debayle, and he is glad to note that other observers in another country have had the same experiences.

Dr. Martinez of Havana remarked that the fevers described by Dr. Debayle are similar to what is called in Cuba enterosepsia, and in his opinion are nothing more than cases of Malta fever; and that some of these cases described by Dr. Debayle are light cases of malarial fever, with an added infection of Malta fever. He claims to have seen such cases in Havana.

Dr. Coronado believes that these fevers, as described by Dr. Debayle, are nothing more than prolonged remittent malarial fevers.

Dr. Caluck, who has practised for twenty years in Costa Rica, has observed the same forms of fever in his practice. He believes that this prolonged fever exists from Mexico to Panama.

Dr. Perna of Cienfuegos believes that these fevers are not alone found in the tropics, but that he remembers a description of a fever by Dr. Robert of Barcelona similar to this, and designated by him as simple infectious fever. He does not believe that they are paludic or malarial, on account of their benignancy and because of the fact that they are not influenced by quinine.

Dr. Fernandez of Puerto Rico stated that he practises in a region where malaria is unknown,

and that he has had occasion to observe many cases of this fever.

Dr. Guiteras said that he believes he was the first to publish observations of this form of fever in the annals of the Marine Hospital Service in the United States in the year of 1881. He described it under the name of continuous thermic fever. He believed it was due to the disarrangement of the thermic centers, but abandoned this theory when he noticed in Key West that this fever was transmissible; he then believed that it was an infectious fever. He has never found the hematozoan in the blood, and lately he is inclined to believe that they are cases of Malta fever, as he saw a case recently in Philadelphia in an officer who had returned from Puerto Rico. In regard to secondary infections, a term so commonly used in this country, he does not believe that they are brought about by coli bacillus, as this is a pyogenic organism, and the formation of abscesses is very rare in these cases.

Dr. Garcia of Havana has seen many similar cases in the "Quinta de Dependientes," and has never been able to demonstrate the present of the hematozoan in the blood. They never respond to quinine or intestinal antiseptics.

In closing the discussion, Dr. Debayle said that he believed at first that these fevers were typhoid; in other cases that they were tuberculosis; in others that it might be probably cases of Malta fever. But he is convinced that Malta fever, with its typical remission in the 21st day, exists in Nicaragua, while in the cases he had just described, the temperature is never remittent or reduced to normal. The symptoms are distinct from those of Malta fever. He intends to make new investigations in regard to this fever on his return to Nicaragua.

Borras Fever.—Dr. Luis Perna of Cienfuegos read a paper on this subject. This disease is a very grave fever. It usually attacks children, but sometimes the aged. It is characterized by black vomit, in small quantity, or very abundant, which may come on immediately following the initial fever, or several days after. Very rarely is it accompanied by albumin, and never by epistaxis, melena, hiccough or icteric discoloration; it may attack the same person more than once; both whites and negroes are susceptible; it is malarial in origin, and consequently its rational treatment is quinine. Analysis of the blood has always demonstrated the presence of the malarial parasite. It is different from yellow fever in that it is not contagious and not accompanied by albumin, hiccoughs, epistaxis nor icteric discoloration.

Dr. Edelman is of the opinion that borras fever is a syndrome and not a pathological entity. He has seen cases which were clearly those of yellow fever and others which were undoubtedly cases of malaria. He has never observed cases due to typhoid fever nor profound lesions of the gastro-intestinal tract.

Dr. San Martin does not believe that borras fever is a pathological entity, but a symptom which may present itself in other fevers as in yellow fever or malaria.

Dr. Dueñas did not discuss what borras fever is, but later on will take up this subject in a paper which he is to read on the diagnosis of yellow fever in the native Cuban. But he referred to the fact that Kelock, Kierner and Loupy have described the severe hemorrhages from the mouth which take place in the hemoglobinuric bilious fever.

Dr. Moreno does not believe that borras fever is a paludic fever. He believes that it is a form of yellow fever in natives.

From the results of these discussions it was evident that the same difference of opinion exists now in regard to the duality of yellow fever and borras fever. Many native physicians are of the opinion that it is a peculiar fever which attacks children; others, that it is a form of malaria; still others that it is a symptom of various conditions; while the majority believe that borras fever is yellow fever in the native.

Etiology of Yellow Fever.—This was the title of a paper by Drs. Walter Reed, James Carroll and Aristedes Agramonte, Acting Assistant Surgeons, U. S. Army. In a preliminary paper read before the American Public Health Association, at its meeting at Indianapolis, Ind., October 22-26, 1900, the authors arrived at the conclusion, based on observations made by them that the mosquito was the intermediate host for the parasite of yellow fever. In this additional note they presented the results of their further investigations on this important subject, which have been continued at an experimental sanitary station (Camp Lazear) near the town of Quemados, Cuba. At this station, in strict quarantine, and with every source of infection absolutely excluded, they succeeded in infecting 85.71 of those individuals who have been bitten by purposely-contaminated mosquitoes (*Culex fasciatus*. Their observations do not conform with the opinion that mosquitoes carry the specific agent in their proboscis, and simply transfer it from one individual to another in a mechanical way, but appear to demonstrate that the parasite of this disease must undergo a definite cycle of development in the body of the mosquito before the latter is capable of conveying infection. This period would seem to be not less than twelve days. The question of house infection is also considered, and it is shown that this infection is due to the presence of mosquitoes that have previously bitten patients suffering from yellow fever; and that the danger of contracting the disease may be avoided in the case of non-immune individuals who sleep in this building by the use of a wire screen. It was also demonstrated by observations made at this camp that clothing and bedding contaminated by contact with yellow-fever cases, or by the excreta of these patients, are absolutely without effect in conveying this disease. The following conclusions were reached: (1) The mosquito (*Culex fasciatus*) serves as an intermediate host for the parasite of yellow fever. (2) Yellow fever is transmitted to the non-immune individual by a mosquito that has previously fed on the blood of those ill with this disease. (3) An interval of about twelve days or more after contamination appears

to be necessary before the mosquito is capable of conveying the infection. (4) The bite of the mosquito at any earlier period after contamination does not appear to confer any immunity against subsequent attacks. (5) Yellow fever can also be experimentally produced by subcutaneous injection of blood taken from the general circulation during the first and second day of this disease. (6) An attack of yellow fever, produced by the bite of the mosquito, confers immunity against a subsequent injection of the blood of an individual suffering from the unexperimental form of this disease. (7) The period of incubation in thirteen cases of yellow fever averaged from forty-one hours to five days and seventeen hours. (8) Yellow fever is not conveyed by fomites and, hence, disinfection of articles of clothing, bedding and merchandise, supposedly contaminated by contact with those ill with this disease, is unnecessary. (9) A house may be said to be infected with yellow fever only when there are present within its walls contaminated mosquitoes, capable of conveying the parasite of this disease. (10) The spread of yellow fever can be most effectually controlled by measures directed to the destruction of mosquitoes, and the protection of the sick against the bite of these insects. (11) While the mode of propagation of yellow fever has now been definitely determined, the specific cause of this disease remains to be discovered.

The discussion was opened by Dr. Perna who said that it is sophism to believe that *post hoc, ergo propter hoc,* that is to say, as Carmona, Freyre, Sanarelli and others have fallen to this error, one must not be too precipitate in accepting the result of statistics. He stated that the studies made of mosquitoes are very old, and that a French doctor, who died about the year of 1850, expressed the opinion that malaria, yellow fever and cholera were propagated by mosquitoes. Dr. Perna also criticised the methods employed by the Commission in making experiments on human beings and stated that he is entirely opposed to such experiments.

Dr. San Martin defended eloquently and with strong arguments the high scientific standard of the experiments as carried out by this Commission, and also brought out the point that it was not statistics, but facts that this Commission presented.

Dr. Holbeck was particularly interested in the paper and expressed his opinion that the problem of 200 years was about to be solved and that the old quarantine regulations should be greatly modified. He also described the existence of a pine belt within a short distance of Charleston, S. C., in which yellow fever never developed as an epidemic; although patients ill with the disease would go there during the existence of epidemic in Charleston and would die from the disease, it would not spread. Mosquitoes are not known in that region, and probably this is the true explanation of the above fact. He concluded by emphasizing the inestimable value of these experiments if they proved to be true.

Dr. Martinez supported Dr. San Martin's views. He took up the moral question and claimed that without these experiments the truth could not have been discovered.

Dr. Guiteras who, up to within a short time had been adverse to the theory of the transmission of this disease by mosquitoes, now accepted as incontrovertible the results of the experiments of the Commission. He followed with interest many of the experiments, and as a member of the Commission saw most of these cases, which he had no hesitation in pronouncing typical cases of yellow fever. A fact which impressed him forcibly was the absolute control of the epidemic by Dr. Reed. The cases would develop or not as he wished. He does not think that the mosquito should be called the *Culex fasciatus.* Giles' description of the *Culex tiniads* mosquito agrees more closely than with the *Culex fasciatus.* He describes the difference between them. He is inclined to consider them a genus apart, because they lay eggs different from the other form of *Culex.*

Dr. Finley stated his admiration for the work of the Commission. He said that he believes that this session of the Congress will go down in history as of great importance. He believes that the differences between his opinion and that held by the Commission will disappear in the course of time. He states that they were based upon the fact that he investigated with three varieties of mosquitoes, while the Commission has been restricted to one variety; that the Board was placed upon better footing for obtaining satisfactory results; that the negative result obtained by the inoculation of mosquitoes of short infection should not induce the Commission or the Board to make such hard and biased rules as are evidenced in its conclusions.

In conclusion Dr. Reed said that he was profoundly impressed with the interest and attention given to these experiments. In regard to the moral aspect of the case, he did not think that any one appreciated the position in which he found himself nor the difficulties which beset his path. The first experiment was made on a member of the Board, Dr. Carroll. The senior member of the Board expected to take his bite in turn, but was unexpectedly called North. As no animal could be given the disease, and it was useless to follow the previous indefinite experiments, it was absolutely necessary to make these experiments on human subjects, or otherwise volumes could have been written and discussed and yet one would have been no nearer the truth than at first. No progress could have been made toward an exact knowledge of the disease unless human subjects were used. All experiments were performed upon persons who had given their free consent. In reference to the remarks of Dr. Holbeck of Charleston, he did not say that the disinfection of vessels should be dispensed with; but only referred to such articles as bedding and clothing. It is necessary to get rid of the mosquitoes, and this simplified the process of disinfection. In regard to the remarks of Dr. Guiteras in reference to the name of the mosquito, Dr. Howard of Baltimore told the speaker that *Culex fasciatus* is identical with *Culex tiniads* as described by Giles. Theobold separates *Culex tiniads* from the genus *Culex* and places it in a new genus, *Stegamina.* These lay their eggs in a peculiar way, and there is also a

difference in the anterior claws of the male insect from those of the other *Culex*. There is also a difference in the larva of the *Culex fasciatus*. It is very interesting also to note the fact that this is the very mosquito that Dr. Finley used in his experiments and that this particular mosquito does not belong to the genus *Culex*; therefore, malaria has a genus of its own, namely, *Anopheles*, and yellow fever, the genus *Stegamina*.

Yellow Fever.—At the afternoon session Dr. Pedro Albarran of Havana described an epidemic of yellow fever which occurred in San Diego del Valle, Province of Santa Clara, twenty years ago. Out of a population of 300 inhabitants, 61 were attacked and 48 died. The interesting point about this epidemic was that native Cubans, both blacks and whites, suffered most from the ravages of this disease. The disease was traced to a Spanish soldier who died in the outskirts of the town three days after his arrival. The Cuban who nursed and buried him developed the disease five days after. The epidemic lasted all summer and cold weather stopped it. Only two cases occurred during the following spring.

At the Thursday morning session a paper on Prophylaxis in Yellow Fever was read by Dr. José A. Trémols of Havana.

Dr. Liston H. Montgomery of Chicago proposed a new office in the National Cabinet, namely, a Department of Health.

Dr. Ramon Guiteras read the paper of Dr. Alvah H. Doty, Health Officer of the Port of New York, entitled The Necessity for a More Careful Investigation as to the Cause of Outbreaks of Infectious Diseases. The promptness with which an outbreak of infectious disease is brought under control or suppressed depends principally upon our knowledge of the means by which it is transmitted. The doctor emphasized the fact that, whereas the laity and many of the medical profession believe that the clothing actually worn by *well* persons is a usual medium of infection, careful investigation shows that this occurs only in rare instances. Experience teaches that it is the mild, ambulant or convalescent cases which are unrecognized as the carriers of infection. He cited the recent epidemic of smallpox in New York City, and referred to the numerous mild ambulatory cases. Mild or ambulatory cases of infectious and contagious diseases constitute a greater menace to the public health than those well marked, inasmuch as they frequently are not recognized or looked for. Another fact to be borne in mind is that infectious diseases are generally contracted by being in contact with cases of a like character. His conclusions are as follows: He is satisfied that the clothing of well persons and the cargoes of ships are rarely the means of transmitting disease. . . . It is the mild, ambulant or convalescent cases which pass unrecognized, "but this does not imply that we should relax our efforts to protect the public health, but should bring about a more careful and thorough investigation as to the means of transmission of infection."

Dr. Moreno of Havana thinks that the subject is important and believes that more attention should be directed to the cases of relapse in yellow fever which may occur after fifteen days. When they occur the cause is attributed to infected objects. Diphtheria he believes can be transmitted by the clothing of healthy persons.

Dr. John Guiteras said he considered Dr. Doty's paper as the first plausible expression of modern quarantine ideas. Since 1881 he has always said that the first case of yellow fever reported is not the first case of the epidemic. He has demonstrated not only previous mild cases but evidences of fatal cases occurring before the first recorded case. The importance of mild cases in connection with yellow fever is great and the negro is often sick and the disease unrecognized. One of the sources here is the native-born child. Scarlet fever is especially difficult to recognize in negroes. One epidemic in Savannah was due to mild cases in negroes. He congratulated Dr. Doty on the excellence of his paper.

Dr. Marcour requested information as to life of mosquitoes. Dr. Agramonte stated that mosquitoes hibernate and live from fall to spring. Dr. Porter of Florida cited a case in which eleven out of a crew of fourteen died of yellow fever before reaching Rio. The captain stated that no mosquitoes were on board. The question brought up by Dr. Doty is not *new*. It has long been believed that sunlight and air are Nature's disinfectants.

Dr. D. T. Lainé of Havana does not think that much stress should be laid upon the observation of physicians when made so long ago as twenty years, as in the case cited by Dr. Porter. Not long since in company with Dr. Guiteras he went on board the "Mexico," then lying in the Bay of Havana. The captain and crew assured them that there were no mosquitoes on board and yet they found several dozen in different staterooms. Mistakes in the diagnosis of cases are frequent.

Dr. Halbech of Charleston believes that the whole history of yellow fever is to be rewritten and recommends each one present to use his good offices on his own government toward having this commission appointed.

Madura Foot.—Drs. A. Diaz Albertini and C. M. Desvenine of Havana reported two cases. One of the cases was shown and the amputated foot of the other case. A description was given of the parasite found in the granules, *Streptotrix Maduræ*, and microscopic preparations were shown.

Dr. Calmech of Costa Rica has seen many cases in Costa Rica where it is confounded with elephantiasis. He believes the disease can be cured in the beginning when the nodules are small. He claims that elephantiasis is rare, but the Madura foot very common.

Dr. Debayle of Nicaragua has seen many cases in his practice. Dr. Moreno does not think that the absence of filaria in a suspicious case should prove the absence of elephantiasis.

THE VALUE AND ACCURACY OF THE ROENTGEN METHOD OF DIAGNOSIS IN CASES OF FRACTURE.[1]

BY CHARLES LESTER LEONARD, A.M., M.D.,
OF PHILADELPHIA.

A DEMONSTRATION of the accuracy and value of this method in the diagnosis of fractures is probably the most useful view which one can take as a subject for discussion. It serves to show, in part, that the errors which have been attributed to this method are in reality due to its inaccurate employment and the misinterpretation of the results obtained.

The accurate mechanical principles employed in securing the data upon which a diagnosis by the Roentgen method is based insure absolute results when the technic of its employment is correctly understood, and the data obtained by its use rightly interpreted. These data, the skiagraphs, have the advantages of mechanical production and permanence; they can be studied by one or more observers and compared with the normal, or other pathological cases. Anatomical and surgical knowledge are as essential to the accurate employment of this method of physical diagnosis as they are to other methods. They must, however, be combined with the necessary technic in handling the apparatus and the clinical experience which fits the observer to deduce the correct diagnosis.

Such technic is essential to the employment of all the mechanical devices employed in physical diagnosis. It is as true of the laryngoscope, the ophthalmoscope and the clinical thermometer as it is of the Roentgen-ray apparatus.

The treatment of fractures by the ordinary methods has produced good functional results in the majority of cases. There is, however, in the practice of the most experienced surgeons, a proportion of cases in which the results are not at all satisfactory, and a still greater proportion in which there is, in spite of fair functional results, a wide field for improvement.

Lane of London, among others, has shown that even slight alterations in the symmetry of the skeleton, especially in the lower limbs, give rise to an unsteadiness in the gait that incapacitates the patient for the pursuance of his calling, if balancing on the feet and security in walking are at all essential. As a consequence of his studies, he has operated in many cases of simple fracture in which he found it impossible to secure complete reduction or to retain the fragments in accurate apposition. The conditions of mechanical obstruction found during these operations proved that satisfactory reduction and retention would have been absolutely impossible by any other than an operative method.

In reference to these cases, he says: "In every simple fracture in which it is important to the individual that the original form of his skeleton shall be retained and his mechanics suffer no alteration, the surgeon should, failing to obtain accurate apposition, as determined by the radiograph, cut down on the seat of fracture and restore the bone or bones to their original form. He must not be satisfied with what is clinically called 'good position,' when by operation he can obtain a perfect result, and in the case of the leg this is particularly important."

There is undoubtedly a large percentage of fractures in which the results can be vastly improved if the methods of diagnosis and treatment are reduced to a scientific, rather than an empirical, basis. The Roentgen method of diagnosis has shown that many fractures that were considered rare exist in a much greater proportion than was suspected, and that the functional loss which was supposed to result from a traumatism or sprain, and was termed traumatic arthritis or a "bad sprain," is often in reality the result of an undetected fracture, which it was impossible to diagnose by other methods of examination. In one instance that has come under my observation, a lady who had received a severe injury of the ankle, desired a skiagraphic examination, as "there had been so many 'bad sprains' in her family." The skiagraph showed that there had been a fracture through the external malleolus which had escaped detection, because of the extreme swelling that followed very rapidly after the injury. In another case a diagnosis of fracture of the fibula was made, and the foot placed in plaster of paris. The functional result was far from good. A skiagraphic examination showed that, instead of a fracture of the fibula above the malleolus, the fracture was through the external malleolus, entering the joint, while the tip of the internal malleolus had also been fractured, the fragment lying in such position as to entirely escape detection.

Not only have unsuspected fractures been frequently detected, but multiple fractures also have been shown to be present where only one was suspected. In addition to the detection of fractures that are only suspected, this method of diagnosis has other advantages which are exceedingly valuable. The exact line of the fracture is determined. This enables the surgeon to set the fracture with greater facility and to guard against the production of deformities which the shape of the fragments show are mechanical possibilities, or the position of the fracture line leads the sur-

[1] Read by invitation at the annual meeting of the Mercer County Medical Society, held at Trenton, N. J., November 13, 1900.

geon to suspect may arise from the formation of exuberant callus. Thus, in oblique fractures, overlapping and shortening are the dangers to be avoided; in transverse fractures, angular deformity is to be feared; in spiral fractures, a rotation of one fragment on the other is liable to take place: while in fractures that involve the joints, a restriction of motion may result from a malposition of the fragments or the interference with motion due to excessive callus formation. Another advantage is that more accurate information is obtained, and without manipulation. The patient is spared unnecessary pain, while the injured tissues receive no further traumatism, and instead of being devitalized, their recuperative forces are conserved. In addition, the number of fragments, their form, their position, the amount of displacement or shortening, and the presence of small comminutions that are liable to prevent firm union, are all detected by a good skiagraph and render the exact coaptation of the fragments more certain and easier, or determine the impossibility of complete reduction without operative intervention.

This increased facility in diagnosis is not, however, the limit of usefulness in the application of this method to fractures. The accuracy of the setting and the efficiency of the fixation apparatus, or other method of treatment, can readily be determined. In four cases of fracture of the femur that have lately been examined by the Roentgen method, there was overriding of the fragments, and, although the length of the two limbs was equal, there had been no coaptation of the fragments, nor was this possible. The fracture surfaces were practically transverse, yet so roughened that reduction was impossible. Any union in such a position would have been very imperfect and the functional usefulness of the limb would have been impaired. Operation demonstrated the impossibility of securing coaptation in any other way, and secured complete restoration of function without shortening.

It has of late been so frequently demonstrated that perfect reduction and coaptation are impossible in many cases, or that the present methods of fixation are inadequate, that an ever-increasing number of surgeons are advocating and employing open operation. They restrict these interventions to cases in which the Roentgen method shows that perfect reduction cannot be secured, or that it is impossible to maintain the fragments in position with the ordinary fixation apparatus.

Von Bergmann said at the International Medical Congress that the treatment of fractures had made two very important progressive steps in the past ten years. One is the operative treatment of certain simple fractures, in order to produce more exact coaptation of the fragments; and the other, in the field of diagnosis, through the study of their pathological anatomy and the Roentgen method of diagnosis.

Of those who still oppose the operative treatment of simple fractures, Lane says: "Those who continue to assert that they are able to restore broken bones to their original form can readily substantiate the truth of their statements now by means of the radiograph."

The consensus of the best surgical opinion is now undoubtedly in favor of operation in certain cases of simple fracture. The Roentgen method is the basis for the division of the simple fractures into those requiring operation and those that do not. If the skiagraphs show that the fragments have been properly reduced and held in position by the fixation dressing, operative intervention is unnecessary, but when the skiagraph shows that the attempts at reduction and coaptation have been ineffectual, operation should be undertaken, or, at least, as Lane says, "in any case, the patient should have the facts, including the radiographs of the fracture, in the best possible position, laid clearly before him, and he should be allowed to choose which form of treatment he prefers."

The advantages of such a course are very evi-

Fig. 1.—Linear fracture of tibia without displacement.

dent. The advent of the Roentgen method into the diagnosis of fractures has created a higher standard by which the results obtained in the treatment of fractures must be judged. The practitioner can no longer be said to have employed all the means and knowledge to the best of his ability in the treatment of a fracture unless he has employed, or suggested to his patient the employment of, the skiagraph. In addition, if the skiagraph shows that perfect coaptation and fixation have not been secured, he must at least offer his patient the alternative of operative intervention and employ it if it is desired.

The skiagraph has been admitted as evidence. Undoubtedly, many suits for damages will be based upon its findings. The safety of the practitioner lies in its employment to prove that the reduction and fixation have been accomplished, or, if not, he should have proof that he suggested its employment to the patient and was refused its aid. The skiagraph, however, can never form the basis upon which the amount of damages is as-

sessed. That will depend as formerly upon the functional disability and loss which the patient has sustained. It can only form a part of the evidence, as it does not take cognizance of the injury which has taken place in the soft tissues, although much may be inferred from the relative position of the bones about a joint.

Whenever a skiagraph is introduced as evidence, the defendant should demand the privilege of having a similar examination made, and should employ expert testimony to fully explain its meaning to the jury. It is especially in this connection that the accuracy of this method has been brought in question. Is the skiagraph absolutely certain to detect a fracture? Does it represent relatively the amount of osseous injury? Is the distortion so great as to make it unreliable?

It can be stated definitely that all fractures in the limbs can be detected. This method, however, has as yet its limitations and, while fractures

Fig. 2.—Fractures of external and internal malleoli.

of bones in the body may be detected in favorable cases, they cannot at present be excluded. From what has already been said regarding the technic and knowledge necessary to properly employ this method, it can be readily understood that the detection of all fractures in the limbs can only be made by those competent to employ this method accurately. When, however, a negative is secured in which the cancellated structure of the bones can be distinctly seen, the presence or absence of all fractures can be determined beyond a doubt. The detection of the minute linear fractures in the accompanying illustrations shows the possibilities of this method, and it is certain that no fracture would have escaped detection in either of these negatives.

Again, with a technic capable of producing such detail, it is evident that the apparatus has been employed in such a manner as to portray the entire amount of injury and to preclude the idea of distortion. It is, of course, possible to produce distortions and exaggerations; they can be produced in any method of physical diagnosis. They are, however, readily recognized by a competent critic.

One of the great advantages of this method is the possibility of establishing an absolutely negative diagnosis. This is possible in all suspected fractures of the limbs. Such a negative diagnosis is invaluable to the patient. Without it he must undergo the inconvenience and expense which are necessitated by fracture treatment.

The treatment of a limb, suspected of fracture, as if a fracture existed can no longer be considered good surgery and will hereafter lay the practitioner open to the suspicion of exaggerating the severity of the injury which he has been called upon to treat.

These examinations are thus invaluable in the diagnosis and treatment of fractures. They cannot be made correctly and have their true value, except by an observer who has acquired special technic and clinical experience in conjunction with his professional education. Every medical society and medical community owe it to themselves and to their patients to see to it that some one of their number possesses the knowledge requisite to the correct employment of this method for the benefit of the community at large.

PHARYNGEAL ADENOIDS AND HYPERTROPHIED TONSILS.[1]

By J. H. WOODWARD, B.S., M.D.,
OF NEW YORK.

Pharyngeal Adenoids.—In November, 1869, an English translation of Prof. Wm. Meyer's essay on Adenoid Vegetations was read before the Medico-Chirurgical Society of London. The existence of such growths had been noted before in perhaps half a dozen cases, but, until Meyer had published his observations, the common occurrence and the clinical significance of them had not been appreciated by any one. It is extraordinary that such simple and easily discovered truths should have remained undiscovered so long. But it is more extraordinary still that, after so careful and so complete a description of this important and common condition of the nasopharynx had been given to the world by Meyer, nearly twenty years should have elapsed before the profession in this country was aroused to a real sense of its importance by Hooper. During the last decade, the literature of pharyngeal adenoids has become voluminous. And yet, I am constantly confronted by evidence that it is still advisable to emphasize the importance of this topic, which some of us may be tempted to look upon as too hacknied for further serious discussion.

In a paper on the Prevention of Intracranial

[1] Read before the Rutland County (Vt.) Medical and Surgical Society, July 10, 1900.

and Intravenous Complications in Suppurative Diseases of the Ear, which I read before the New York County Medical Association in April, 1900, the following paragraph may be found: "The importance of diseases of the nose and throat as predisposing causes of suppurative diseases of the ear should not be forgotten. The existence of hyperplasia of the lymphoid tissue in the vault of the pharynx tends to provoke acute suppuration in the middle ear, and provides a condition favorable to recurrences of the attack. Attention has been directed to these facts by numerous writers; but the lesson has not been learned even by many who are desirous of being known as specialists in otology. Among close observers, there can be no doubt that, in patients under fifteen, an adenoid exists in almost every case of suppuration of the ear. To have any etiological bearing, however, it must promote a chronic congestion of the nasopharynx. But, in order to serve that purpose, the growth need not be very large, although the greater the adenoid the more likely will it be to cause trouble in the ears." These observations embody conclusions drawn from a personal experience in this class of cases beginning in 1885, when I performed my first operations upon pharyngeal adenoids. They are confirmatory of the conclusions reached by Meyer thirty years ago, and coincide with the subsequent experiences of other competent observers.

In the first place, therefore, I would insist that the *excitation of aural disease* is the chief mischief attributable to the existence of pharyngeal adenoids. In their presence, we may encounter deafness without inflammatory invasion of the tympanum, the deafness being due to direct occlusion of the orifices of the Eustachian tubes by the adenoid growth, or to a sequential Eustachian catarrh. In other cases, we may find that the tympanum is the site of a catarrhal inflammation, which may be either acute or chronic. Or, quite as often, we have to deal with an acute or a chronic suppurative disease of the middle ear, with perforation of the drum-head and the other classical symptoms of purulent otitis. These various diseases of the ear in patients under fifteen years of age indicate, first, that an examination for adenoid vegetations in the nasopharynx should be made; and, secondly, that such growths should be removed when they exist, whether they are large or small. It is possible that the otitis may subside, and the function of the ear be restored, in a limited number of cases, without the adenoid operation. But such cases are sure to relapse, and relapses are very deleterious to the function of the ear. Moreover, such recurrences of purulent otitis media may be followed by infective meningitis, sinus thrombosis, or abscess of the brain. The occurrence of those pathological states as consequences of otitis, though rarely justifiable, is generally due in these days to scandalous procrastination and timidity.

The deleterious influence of adenoids upon the patient's general health is a consequence second in importance only to the condition we have just considered. Many of these patients are pale and anemic. The processes of nutrition are imperfectly performed. The patients are dull and listless. The intensity of the symptoms varies with the size of the adenoid growth, being especially marked when the nasopharynx is completely occluded. Obstruction to nasal respiration is doubtless the chief reason for degeneration of the health. But it has seemed to me sometimes that mechanical obstruction of the upper respiratory passages alone is not a sufficient explanation of the phenomena. It has seemed likely that the adenoid may secrete a poisonous substance, the absorption of which may account for some of the changes in the patient's general condition. At all events, it is wonderful what a change is wrought for the betterment of the health of adenoid victims by a thorough removal of the growths. The changes are among the most striking that are ever observed in the medical world. The child speedily casts off the signs and suggestions of malnutrition and dyscrasia. The anemia vanishes; the power of digestion becomes sufficient; and the dull and listless habit is replaced by a normal buoyancy of spirits; while by day and by night, as well, the nasal respiratory function is noiseless, complete, and regular.

Supplementary to what has already occupied our attention, we may consider the symptomatology of pharyngeal adenoids from the following standpoints: (1) Symptoms common to all cases of adenoids; (2) symptoms dependent upon the size of the adenoids; and (3) occasional accessory symptoms.

1. *The symptoms common to all cases of adenoids are* (*a*) hyperplasia of the lymphoid tissue in the vault of the pharynx; (*b*) chronic congestion of the submucous blood-vessels of the inferior turbinated body; (*c*) a more or less profuse mucopurulent discharge.

If one may draw conclusions from reported cases, it is apparent that some operators have overlooked the fact that a certain development of lymphoid tissue in the nasopharynx is normal and necessary to the patient's well-being. The so-called Lushka tonsil is not a pathological structure. It becomes a pathological structure only when it has undergone hypertrophy or hyperplasia. Its function is to secrete mucus for the lubrication of the nasopharynx. And when its function fails, as it does in many cases of chronic nasopharyngitis, it is well known how dry the pharynx becomes and how wretched that state makes the patient. We should have no patience, therefore, with operators who remove the normal structures of the nasopharynx (even down to the periosteum in some reported instances), for the final state of their victims must have been a discredit to the operator and to surgery in general. A brief study of the anatomy and physiology of the nasopharynx, and a short experience in palpating that region in health and in diseased conditions, will enable any one endowed with common sense to differentiate a normal state of the nasopharyngeal structures from an hyperplasia

of the pharyngeal tonsil, however slight the hyperplasia may be.

Hyperplasia of the pharyngeal tonsil varies in degree in the different cases. In some, it amounts to a more or less boggy thickening of the covering of the superior posterior wall of the nasopharynx. In others, the whole nasopharyngeal space is filled with vascular boggy masses, resembling the softer hypertrophies of the faucial tonsils. Between these extremes, we find many grades of development. The adenoid may be sessile and single, or it may be composed of many pendulous parts. It may contain sufficient connective tissue to suggest a fibroid growth. Associated with adenoids, we generally find a chronic congestion of the submucous blood-vessels of the inferior turbinated body. This constitutes a chronic vascular hypertrophic rhinitis, which, upon removal of the obstruction in the nasopharynx usually subsides without further treatment. A more or less profuse mucopurulent discharge from the nasopharynx appearing on the posterior wall of the oropharynx, and sometimes at the nostrils, is common to these cases; and its existence should excite suspicion of the presence of an adenoid.

2. *The symptoms dependent upon the size of the adenoid are* (*a*) alteration of the voice, as if the patient were suffering from a cold in the head; (*b*) mouth-breathing; (*c*) snoring and choking in sleep; (*d*) general malnutrition; (*e*) deafness; and (*f*) chronic headache and mental dulness.

These symptoms vary in intensity in every case. During the summer months they are very much less marked, as a rule, than during the colder and damper portions of the year. The improvement noted by the parents during the warm weather has often proven delusive enough to effect a postponement of radical treatment to the permanent detriment of the patient's well-being. I am sorry to admit that this responsibility has been shared too often by the family physician.

3. *The occasional accessory symptoms are* (*a*) asthmatic seizures; (*b*) habit (facial) chorea; (*c*) epileptiform attacks. To these may be added the state of deaf-mutism as one of the consequences of adenoids occurring in infancy, for adenoid vegetations occur in the earliest months of infancy, when they not only threaten the integrity of the ears, but sometimes interfere so much with the nursing power of the child as to endanger its life.

A positive diagnosis of pharyngeal adenoids is made by physical examination of the nasopharynx. In certain cases an expert may detect them by anterior rhinoscopy. In a limited number of cases they may be discovered by posterior rhinoscopy. Every unprejudiced physician who is experienced in throat work must realize that it would be hazardous to rely upon that method for the detection of these growths. The method of examination that will surely establish a correct diagnosis in every instance is characterized by thorough and deliberate exploration of the nasopharynx with the finger. Necessarily, the diagnostician must be familiar with the normal and the pathological anatomy of the nose and throat. Objections to digital exploration of the nasopharynx based upon the alleged dangers of injury to the normal tissues, have no especial importance. I have never observed any harm to accrue from that procedure.

Adenoid vegetations are very rarely seen in patients who are more than twenty years of age. For, in a majority of the cases that are allowed to pursue their natural course, retrogression of the hyperplasia takes place during adolescence. It is not proper to wait for this change, however, because during the decade that elapses while it is taking place the patient's hearing may be destroyed and his general health permanently deranged.

Local applications of such alteratives and astringents as tincture of iodine and nitrate of silver may be a sufficient treatment in a small number of special cases, but the real management of pharyngeal adenoids consists in their removal by operation. It seems to me best that an operation should be undertaken in almost every case, whether the adenoid is large or small, for, while in certain patients no important symptoms may be attributable to the growth, one cannot be sure that complications in the ears may not supervene at any moment. The operation for the removal of adenoids, although a serious one, is not especially dangerous. It is true that death has occurred in a few cases of adenoid operations, but the danger of a fatal termination may be almost entirely obviated by careful preparation of the patient for operation, by caution in the administration of the anesthetic, and by celerity and precision in conducting the operative work. Hemorrhage is often profuse for a few moments, but it ceases spontaneously. I regard the administration of an anesthetic as the source of greatest danger in these operations, and I often operate without resorting to one, if I am able to manage the patient properly.

The manner of operating which I prefer, however, is briefly as follows: The child is seated upon my assistant's right knee with its head resting on his right shoulder. Chloroform is then administered until the patient is relaxed, when the mouth-gag is inserted. Then, as soon as I am sure that the patient is not too profoundly anesthetized to swallow, I proceed with the operation, first using the Gottstein curette, which is passed as firmly and as rapidly as possible several times over the region from which the growths project. Blood and detritus are then cleared away from the pharynx, and when the bleeding has subsided, I examine the nasopharynx again with my finger. It is essential that one should be especially careful to note whether the posterior nares are perfectly free, for vegetations hanging close to and obstructing them have often been overlooked, and the operation has failed in consequence. If I find that there are still growths in the nasopharynx that have escaped the curette, I locate them with my finger and remove them

with the cutting forceps, which I devised as a modification of the Loewenberg instrument.

It is rarely necessary for the patient to remain in bed more than a day, even when an anesthetic has been administered. The only after-treatment required, as a rule, is cleanliness of the wound, cod-liver oil, iodide of iron, fresh air, and good food for the general condition. Any residual catarrh of the nose or throat should be eradicated before the patient is discharged. The aural complications must be treated according to their indications.

Hypertrophy of the Faucial Tonsils.—Associated with pharyngeal adenoids, we frequently encounter a hypertrophy of the faucial tonsils. While it is true that the former are often unaccompanied by any increase in size of the latter, hypertrophied faucial tonsils are as a rule, in young subjects at any rate, associated with a more or less marked hyperplasia of the lymphoid tissue in the nasopharynx. The common coexistence of adenoid vegetations with hypertrophied tonsils should never be forgotten. There are, however, many cases of hypertrophy of the faucial tonsils in which no trace of an adenoid may be found.

The aggregations of modified mucous membrane between the pillars of the fauces, known as the faucial tonsils, are normal to the healthy throat. Their function is to secrete a mucus suited to the maintenance of a proper degree of moisture and for the facilitation of the act of deglutition. This is a beneficent function which should be conserved. It has been contended that the faucial tonsils are portals by which the germs of various diseases enter the body. Since the probability that this is often true has not been absolutely established, the integrity of the tonsil should be maintained, unless it has undergone pathological changes that increase its bulk or modify its function.

Hypertrophy of the faucial tonsils is observed especially before the age of puberty. During the period of adolescence resorption of the hypertrophied and diminution in the size of the normal tonsillar tissue is known to take place. But these changes are not universal, for enlarged tonsils are not very uncommon in patients who have passed that stage of development. We are unable to assign any very definite reason for the occurrence of hypertrophy of the faucial tonsils or, for that matter, of the pharyngeal tonsil either. I was once compelled to ablate hypertrophied faucial tonsils in a child eleven months old. But, in general, the existence of the hypertrophy is first noticed when the patient is between the ages of three and ten years.

As is well known the degree of the hypertrophy varies in the different cases, from a slight projection of the tonsillar tissue beyond the plane of the faucial pillars, to an enlargement that reaches to or passes beyond the median line of the oropharynx. The substance of the hypertrophy is strengthened more or less by the presence of connective tissue; and the more abundant the latter, the firmer and more fibrous is the hypertrophied tonsil. In young patients, there is commonly no great proliferation of connective tissue, and the amputated tonsil, although firm, still breaks down easily under pressure of the thumb and finger. In adults, we are more likely to encounter the fibrous tonsil, which is firm and unyielding.

The symptoms that are attributed to hypertrophied faucial tonsils are (*a*) alteration of the voice, in which its tone is muffled, as though the patient were holding something in his mouth; (*b*) snoring and choking in sleep; (*c*) excessive secretion of mucus in the throat; (*d*) frequent attacks of acute catarrhal inflammation in the throat, and follicular tonsillitis; (*e*) chronic enlargement of the cervical lymphatic glands; (*f*) mouth-breathing; (*g*) deafness; (*h*) general malnutrition. Especial attention should be given to the changes observed in the cervical lymphatic glands, for it has happened that a diagnosis of tuberculous infection has been entertained when the enlargement of the glands was due to a non-infectious hypertrophy of the tonsils, or to a simple catarrhal pharyngitis.

The treatment of hypertrophy of the faucial tonsils depends, in a measure, upon the degree of the hypertrophy and the symptoms present. If the patient is subject to frequent attacks of sore throat, follicular tonsillitis, or peritonsillar abscess, even though the tonsils are not markedly enlarged during the period of quiescence, they should be removed by operation, if possible, or reduced in size by applications of the actual cautery, or astringent alteratives. Moderate hypertrophies of the tonsils may not give rise to any very marked symptoms, and they may be treated with the iodine preparations locally and internally. But when hypertrophy is such that the lumen of the oropharynx is materially reduced during the period of quiescence, especially in children, I am convinced that the tonsils should be removed.

The danger of serious hemorrhage after tonsillotomy has given rise to a great deal of discussion, and it must not be ignored. In the first place, a dangerous hemorrhage may be expected in "bleeders" after tonsillotomy, in cases of fibrous tonsils, and during acute inflammations of the tonsil. Severe hemorrhage in other cases is so rare that its occurrence need not be feared.

Hemorrhage after tonsillotomy may be either primary or secondary. Primary hemorrhage may be very profuse for a few seconds, but it usually ceases spontaneously and requires no especial treatment unless an artery of some magnitude has been injured. Spurting vessels may be seized with long-handled clamps, which may be allowed to remain *in situ* for a number of hours, when the artery will have become occluded. Parenchymatous hemorrhage may be profuse, but as a rule it ceases spontaneously. I am convinced that hemorrhage after tonsillotomy is often aggravated by persistent manipulation of the wound in distracted efforts to check the bleeding.

Secondary hemorrhage of a troublesome nature is more common. It occurs a few hours after

the operation and may be profuse and alarming. The exercise of common sense is especially urgent in these cases. The use of styptics is to be condemned, for none of them is potent enough to control a serious hemorrhage, and all of them irritate and inflame the structures with which they come in contact. Direct pressure upon the bleeding part, cording the extremities, the upright position, and rinsing the throat occasionally with hot water containing alcohol or alum, may be tried. Should the hemorrhage really threaten the patient's life, ligation of the bleeding point, or suture of the stump of the tonsil may be done. Or, as a last resort, ligation of the common carotid may be considered, although it is one of the rarest necessities, even in apparently desperate cases.

With the guillotine, we should remove as much as possible of the hypertrophied tonsil, notwithstanding the fact that ablation of a small section will often cause the remainder to shrink to normal proportions. In small and in unmanageable children a general anesthetic will be necessary. As in operations upon adenoids, I prefer chloroform for general anesthesia. Cocaine should not be used in operations upon adenoids; but in patients who are not very young, it may prove serviceable as a superficial anesthetic in tonsillotomy. I do not consider it a safe practice to inject that drug into the substance of the tonsil. In choosing chloroform for general anesthesia, I know that I am somewhat heterodox. It is a well-known fact that ether irritates the respiratory passages and excites an excessive secretion of mucus in the throat and bronchial tubes, especially in the class of cases which we are considering. It is always more difficult to anesthetize such patients, and a relatively larger portion of ether is required to produce the desired effect. This endangers the respiratory center to an appreciable degree. Chloroform does not irritate the air-passages, nor does it cause an excessive production of mucus in the throat and bronchial tubes. A small quantity only is required. A reckless anesthetizer may give an overdose of chloroform, but a properly-instructed and cautious one would not make that mistake. We are all stricken with horror by the reported sudden deaths from chloroform. If, however, those cases had been carefully observed, I am confident that danger signals would have been noted long before the heart was paralyzed by an overdose of the drug. I do not believe that death from chloroform occurs without warning. The results of hundreds of experiments upon animals made by competent men and a rather large personal clinical experience with chloroform alike force me to that conclusion. Chloroform is not as dangerous as it is reputed to be, and ether is less safe, especially when given to children suffering from diseases of the throat, than many of us are apt to assume.

Given a case of hypertrophied tonsils associated with pharyngeal adenoids, shall we operate upon both conditions at the same sitting, and if so, which shall we remove first? The reply to the first question depends upon the individual case. In some instances it is proper to operate upon tonsils and adenoids at the same *séance*; but when the child is not strong and if the growths are large, it is wiser to divide the work between two sittings. Then, the tonsils may be removed first and the adenoids a few days later. Prolonged operations upon the throats of small children are not recommended, for there is danger of causing in them a serious degree of shock. Severe inflammatory complications in the pharynx, larynx, and even in the lungs may be excited by prolonged operations upon adenoids and tonsils. Fibrous tonsils may be extirpated with safety by means of the cold-wire snare. And reduction of tonsillar hypertrophy in "bleeders" may be accomplished by applications of the galvano-cautery.

Up to the present time, I have not encountered a patient on whom a tonsillotomy had been done, who was not benefited, in some measure, at least, by the operation. I have not seen a case in which the quality and the strength of the voice was not improved by removal of the obstructions in the fauces. The alleged evil effects of tonsillotomy upon the organs of generation have not come under my observation.

The post-operative treatment of tonsillotomy consists in keeping the wounds clean. An alterative astringent may be indicated as a local application whenever the process of healing shows a tendency to become sluggish. As a rule, the wounds heal rapidly after operations upon hypertrophied tonsils and pharyngeal adenoids; and cicatrization is complete within a fortnight.

58 West 40th Street.

A REPORT OF SOME CASES OF ABDOMINAL SURGERY, WITH REMARKS ON THE DIAGNOSIS OF CARCINOMA OF THE CECUM AND THE SURGICAL TREATMENT OF CARCINOMA OF THE LIVER AND THE GALL-BLADDER.

By CHARLES GREENE CUMSTON, M.D.,
OF BOSTON, MASS.

(Concluded from page 263.)

Kuester reports a case of resection of the liver and the gall-bladder which was unsuccessful, and this bad result he attributes entirely to the method which he used which was one advocated by Terrier. This consists of passing a large trochar through the parenchyma of the liver and through this thick elastic tubing was carried, and thus elastic ligatures were placed in the liver substance so as to control hemorrhage. The neoplasm was pulled outside the abdominal wound which was left open, but the tumor was not removed. Before doing this the cystic duct had been ligated and cut. The patient died from sepsis and this authority recommends therefore that in the future the tumor should be removed after the application of an elastic ligature.

The two following cases have been reported by

Czerny. The first was a woman thirty-three years old who three months previously had been suddenly attacked by a very severe pain in the abdomen which lasted three days and caused unconsciousness for a quarter of an hour. Four weeks before the operation was performed the patient was again attacked by the same piercing abdominal pains, more marked in the right and left hypochondrium, and these attacks of pain were repeated every day after this. All this time the patient was jaundiced.

A subcutaneous lipoma was found in the right lumbar region, and a resisting mass could also be detected under the edge of the liver at about the level of the tenth rib; this mass was somewhat convex and was directed downward; it was about 3 centimeters wide and was very sensitive to pressure, and a diagnosis of cholecystitis and cholelithiasis was made.

At the operation the lipoma was first removed and then the incision was carried to the median line just below the umbilicus. The gall-bladder was considerably enlarged and had contracted adhesions with the omentum, and after these had been broken down, its surface was found to be full of small nodules. After the gall-bladder had been opened a large number of calculi were removed. The gall-bladder was drawn forward, but was torn by the tension and as the thickness of the wall and the increase in size of the lymphatic glands seemed to indicate a malignant transformation of the organ, it was decided to perform cholecystectomy. The abdominal incision was increased in length and the border of the liver was turned upwards so that the hilus was exposed. The hepatic duct was then directly opened above its junction with the choledochus, and then was closed carefully as possible by sutures. The gall-bladder was then freed up to its insertion with the ductus choledochus and was then tied off with a thick ligature and removed.

At the point where the ligature was applied, the ductus choledochus was intimately united to a lymphatic gland the size of a hazelnut and the incision had been carried directly through it. Another enlarged lymphatic gland was found closely united to the duodenum but it had to be left. The hilus was then plugged with tampons and the abdominal wall was closed with continued silk sutures. The gall-bladder measured 13½ centimeters long and 4½ centimeters thick. The wall in certain places was extremely thick and presented a caseous degeneration; microscopical examination proved that the walls were infiltrated with carcinomatous tissue and the glands had also become involved.

The patient recovered slowly and when allowed to leave the hospital five weeks later she felt in excellent condition. Palpation of the abdomen could not detect any tumor, nor could the enlarged lymphatic gland which had been left behind be felt. The ultimate outcome of this case is unknown, but the author believes that if he had operated immediately after the first appearance of the attack of colic, the metastasis of the carcinoma would have been prevented, while as the case then stood the patient must sooner or later die from the progress of lymphatic metastasis.

The second case operated on by Czerny was a woman of sixty years of age, who for about a year had been apparently suffering from catarrh of the stomach, and who had also had severe pains in the epigastrium more especially in the right. At no time had the patient vomited, nor was there any rise in temperature. The liver dulness began at the seventh rib, and reached in the axillary line to the costal border, and in the middle line 2½ fingerbreadths above the umbilicus; it then projected sharply to the left parasternal line at the level of the seventh rib. Within the boundary of the liver dulness a rather sharp but smooth edge of the liver could be felt, and in intimate connection with it at the outer edge of the rectus a tumor the size of an egg could be detected. This tumor was solid in consistency and its surface was smooth, and it could be distinctly made out as being unconnected from the edge of the liver. When the patient would take a deep inspiration both tumor and liver would be pressed down. Pressure on the growth only produced a moderate amount of pain. The diagnosis of chronic cholecystitis, perhaps malignant disease of the gall-bladder, was made.

The abdominal cavity was opened by an oblique incision in the hypochondrium; the gall-bladder was found to be thickened and after an aspirating needle had been introduced, a seropurulent liquid was withdrawn. An incision was then made into the bladder, and a number of calculi were removed. While attempting to dislodge a stone which was contained in the cystic duct, the tough and thickened wall of the bladder was torn. In the region of the cystic duct there were numerous adhesions with the duodenum, and a nodule the size of a hazelnut was found which could not be peeled out. The cystic duct was tied off and severed in front of this nodule after the surface of the gall-bladder, which was in relation to the under aspect of the liver to which it was adherent to about the extent of a dollar, had been separated with a knife from the parenchyma of the liver. The parenchyma which was removed at this time was about a centimeter in thickness. The opening of the cut surface of the cystic duct was closed by two sutures.

Sutures were introduced into the liver substance in order to close the raw surface, but as they cut through, all attempt to closing off the liver was given up and the cavity and raw surfaces of the liver were packed with iodoform gauze. The patient recovered nicely from the operation and was discharged at the end of two months, but it was learned that death occurred a few days later. The length of the extirpated gall-bladder measured ten centimeters and in breadth it was 5½ centimeters. Its walls, especially near the fundus, had become greatly thickened, and were studded with nodules and were very tough; microscopical examination did not demonstrate

that this was clearly a case of carcinoma of the gall-bladder.

Heidenhain describes a case of carcinoma of the gall-bladder in a patient sixty-one years old, who had been suffering from cramp-like pains in the region of the stomach, and which shot up into the chest and became exceedingly severe in the back. By palpation the liver dulness was found to begin at the upper border of the fifth rib and extended as far as the mammillary line at the costal border. The lower pole of the gall-bladder, which was the size of a goose egg, was spherical, but one could detect a slight irregularity on its surface. Its outline could be made out fairly well. The movements of respiration imparted movements to both the liver and the tumor.

The abdomen was opened by longitudinal incision carried along the border of the rectus muscle and, after the adhesions with the omentum had been broken down, the enlarged gall-bladder along with the contiguous structures was drawn out through the incision. The fundus of the gall-bladder projected somewhat above the lower edge of the liver and calculi could be plainly felt in its cavity. As cholecystitis was supposed to be present, the bladder was opened for the purpose of removing the stones, but in doing this a necrotic growth the size of a walnut was found in the interior, so that the incision in the gall-bladder had to be closed with a continued catgut suture. The liver tissue which was lying in direct continuity with the gall-bladder was resected, because connective tissue changes had already taken place in it, and a wedge-shaped piece about 10 or 12 centimeters in size was removed by the thermocautery. At the point of section the liver appeared to be perfectly normal in color and consistency, and no secondary foci of disease were to be seen. The resection of the liver was accomplished without any hemorrhage, and only one small vessel had to be ligated.

The cystic duct was ligated and cut, and its end was closed by Lembert's sutures and a bit of the omentum was fastened over it. After this the adhesions with the parietal peritoneum and omentum were stitched together so that the abdominal cavity was in part walled off from the wound of the liver.

A calculus almost the size of a walnut was found lodged in the fundus of the gall-bladder, while a large number of smaller stones were found in the cavity of the organ. The carcinomatous growth had started from the mucosa of the fundus, and had from there extended to the liver. The patient was discharged in excellent condition at the end of October, there remaining only a small granulating wound. Two months later the patient was obliged to take to her bed, and examination showed nodular deposits of the growth in the liver.

Mr. Mayo Robson has four times operated for carcinoma of the gall-bladder, and secondary deposits of the growth in the liver. He did a cholecystectomy and resected the liver in these cases. A more detailed account of them will be found in Mr. Robson's recent book upon Surgery of the Gall-Bladder.

Marchand performed cholecystectomy for carcinoma of the gall-bladder in a woman sixty-four years old, and Socin has reported the following case. A woman sixty-three years old presented a tumor situated below the right costal border which had been present for about eighteen months. An abdominal incision showed that the tumor was the gall-bladder which had become extensively adherent to the liver, stomach and transverse colon. A resection of the colon was performed and then the tumor could be separated from the stomach. A calculus was present in the cystic duct and was removed by a longitudinal incision, and the duct was then closed with sutures. The gall-bladder was then separated from the liver by breaking down the adhesions binding it to it; the ductus was then cut and immediately closed with sutures. End to end anastomosis of the colon was done, and the gall-bladder removed. The patient recovered.

Ullmann has reported the following interesting case. The patient, who was fifty-four years old, had been complaining for about two weeks of pain in the right hypochondrium which she attributed to a cold. Examination showed that this side of the abdomen contained a very hard and irregular mass which was movable and was displaced by the movements of respiration. Everywhere above the tumor dulness on percussion corresponded to the liver dulness which began at the seventh rib, while downwards and to the left the dulness finally changed to a tympanic resonance.

A diagnosis of carcinoma of the liver, or possibly a malignant growth of the omentum extending to the liver, was made. The abdomen was opened by an oblique incision carried over the mass; the growth proved to be a much enlarged gall-bladder. The walls of the organ were very rigid, but by palpation liquid and calculi could be felt in the cavity of the organ. At the point where the gall-bladder was in contact with the liver, the parenchyma of the latter organ had become thickened and hard, and had apparently become infiltrated by the neoplasm of the gall-bladder, especially in the neighborhood of the hepatic duct; no other secondary deposit could be found in the liver, and it was therefore decided to do a cholecystectomy and resection of the liver.

The cystic duct was first ligated and severed and then the hepatic duct was treated, and the diseased portion of liver together with the gall-bladder were removed. Resection of the liver was begun with the knife, but on account of the severe hemorrhage which arose the operator resorted to the Paquelin cautery. As this did not control the hemorrhage, an attempt was made to catch up the bleeding vessels with hemostatic forceps, but this was also found useless, and compression and sutures were also found of no avail. The hemorrhage was finally controlled by closing the liver vertically to the direction of the vessels and then compressing it. Two long myoma

needles were pushed through the folded liver and compression was produced by sterilized gauze.

In order to facilitate the execution of a hepatoduodenostomy the duodenum was sutured to the lower part of the wound and then the parietal peritoneum was stitched to the capsule of the liver, and tampons of iodoform gauze were packed in around the organ.

The gall-bladder when removed was found considerably enlarged and contained a large quantity of calculi; its walls revealed a typical carcinomatous infiltration. The carcinomatous nodule in the liver measured 11½ by 9 centimeters, the thickness of the portion removed being about 4 centimeters. The patient made such a good recovery that at the end of two months Ullmann contemplated performing hepatoduodenostomy, but he was obliged to give this up because a recurrence of the growth had taken place in the liver and the patient died six months alter the operation had been performed.

Ziegler relates the case of a patient forty-seven years old who about three years before coming under observation had been suddenly attacked by cramps all over the body; these attacks of cramps occurred a few times and then did not reappear, and since this time menstruation had stopped. At no time was the patient jaundiced. About a month before seeing the patient she had discovered a hard point in the right upper region of the abdomen, which soon became quite painful. Examination showed that the liver was somewhat enlarged, and in direct connection with it a hard irregular tumor the size of a child's fist could be palpated and which was sensitive to pressure. During the movements of respiration the mass moved up and down with the liver and appeared to be intimately united to it. The diagnosis lay between cholelithiasis with an inflammation of the surrounding organs, or malignant neoplasm of the gall-bladder.

The liver was exposed by an oblique incision carried along the costal border. The gall-bladder was found transformed into a hard irregular tumor which had become closely united to the liver. A nodule the size of a pigeon's egg was found to the left of the gall-bladder which was very white and brilliant as it projected from the parenchyma of the liver in the under aspect of the organ. Other than this there was nothing abnormal in the liver and resection of this apparent malignant neoplasm of the organ was decided on. The cystic duct was ligated and cut, and then a wedge-shaped piece was resected with the thermo-cautery from the liver. A second and smaller nodule was also resected in the same manner. Hemorrhage was considerable and the wounds in the liver were plugged with iodoform gauze. Then the edges of the wounds were brought over the gauze by means of sutures. The gauze was brought out at the upper angle of the abdominal wound and then the remainder of the latter was closed. Microscopical examination of the liver growth showed it to be carcinoma. The gall-bladder contained four large stones, and its walls had undergone a carcinomatous transformation. The patient made a good recovery, but died about five months afterwards from an extensive recurrence of the neoplasm in the liver, cystic duct and neighboring lymphatic glands.

The number of cases published where resection of the liver for carcinoma, and where the gall-bladder has been found normal, are quite few indeed, and Bruns was probably the first who operated for carcinoma of the liver, although he only removed a small section of parenchyma for the purpose of diagnosis.

A very excellent result was obtained by Schrader, inasmuch as his patient was perfectly free from any recurrence of carcinoma of the liver seven years after resection of the organ had been performed. The patient was a woman about thirty years old. Examination revealed a very sensitive swelling protruding somewhat towards the lower part and situated in the right border of the liver, at a point normally occupied by the gall-bladder, and a diagnosis of gall-stones was made.

The abdomen was opened, and at the edge of the liver directly over the gall-bladder a carcinomatous nodule was discovered, being about 4 centimeters wide and 3½ centimeters thick, and caused the border of the liver to appear somewhat protruding. The mass in the parenchyma appeared to be quite limited from the surrounding liver tissue. The gall-bladder which was lying behind it was apparently normal. The growth was removed by means of a large wedge-shaped incision, and the wound was cauterized by means of a Paquelin. The *albuginea* of the liver was carefully united with the edges of the abdominal wound so that the wound in the liver became extra peritoneal. The remainder of the abdominal incision was closed, and the patient made an excellent recovery. The amount of secretion was limited and after about ten weeks the wound was almost completely covered by skin. This operation was performed in 1890 and the woman was found to be perfectly well in 1897.

A very similar case is reported by Luecke. The patient was a woman thirty-one years of age who for two years before the operation had suffered from her stomach, and of late had observed a swelling in the region of the stomach which soon began to give rise to considerable pain. On examination the growth appeared to be about the size of an apple and commenced two finger-breadths below the xiphoid process. Its lower border was sharply defined and it appeared to be globular; no pedicle could be felt; the growth was very movable and gave rise to dulness on percussion. A diagnosis of probable tumor of the liver was made.

When the abdomen was opened the left lobe of the liver was found to be about the size of a man's fist, and was connected with the remainder of the organ by a rather thick pedicle; this lobe was filled with a number of large carcinomatous nodules. The tumor had in part become united to the omentum, in which two enlarged lymphatic glands were discovered. The other abdominal organs appeared to be normal, and it was apparent

that the carcinoma was limited to the left lobe of the liver. It was decided to remove this lobe and consequently, it was stitched to the abdominal incision and then the growth was surrounded by strips of iodoform gauze so as to isolate it from the peritoneum.

Severe hemorrhage resulting from laceration of the liver parenchyma was controlled by passing a rubber drainage tube through and tying off the mass, and this tube was later on replaced by tightly tied ligatures. A week after the operation the pedicle was severed with the thermocautery and at the same time the surface of the liver which was involved was carefully cauterized. The tumor proved to be a carcinoma of the liver. The patient was discharged cured and two years later she was still quite well and without any recurrence.

Jacobs reports the following case. A woman of fifty years of age had been suffering for several years with pains in the right side caused by the presence of a tumor, which on palpation was about the size of an orange and evidently located in the abdominal parietes. The pedicle appeared to be in some way connected with the peritoneum. An incision was made on the right in a line of the greatest length of the tumor, and it was found that the growth had become intimately connected with the surrounding structures. After breaking down adhesions, it was found that the neoplasm was attached to the liver at its lowest part. The growth was removed with the thermo-cautery, a drainage tube was inserted, and the abdominal incision closed. A small fistula remained at the site of the drainage tube for some time, and which gave issue to bile. Six months later a recurrence took place. Histologically the growth proved to be a carcinoma of the liver.

Segond has recorded the case of a large tumor filling the entire pelvis and it varied in consistency in different parts; it extended under the right costal border. The patient was thirty-four years old, and had suffered from severe hemorrhages from the uterus, so that a diagnosis of a fibroid which had in part degenerated had been made. This diagnosis appeared quite justifiable, as no connection with any other abdominal viscera could be ascertained either by examination or from the patient's history. At the operation, it was found that the entire growth was situated on the free border of the liver just above the gall-bladder, and was connected with the liver by a very thin pedicle about five cm. broad; it was nowhere adherent, and consequently could easily be removed. In other respects both the liver and gall-bladder appeared normal, likewise the other abdominal viscera. The patient did not rally and died three days after the operation. The neoplasm proved to be a carcinoma, the lower part of which was softened and degenerated, while the upper part was of a more scirrhous nature.

Roux successfully removed a pedunculated tumor of the liver from a woman aged fifty-four years; the position of the tumor corresponded quite exactly to the so-called processus linguiformis. The tumor communicated on one side with the gall-bladder, and on the other side had made an opening the size of a twenty-five-cent piece in the transverse colon which was situated behind the tumor. This part of the colon was resected along with the growth, and the opening into the intestine was closed by three layers of sutures. At the lower pole of the gall-bladder, where the tumor was adherent, a piece was also removed, and the opening in the gall-bladder was also closed by three layers of sutures, so that a normal sized organ remained. The gall-bladder as well as the growth contained some calculi. The pedicle was resected from the liver, and the rather extensive hemorrhage was controlled first with clamps and then with a double catgut suture.

Keen, Lins, Israel, Von Bardeleben, Müller, Tricomi, Groube, Schmidt, and many other operators have all recorded cases similar to those quoted above, but it would make this paper far too long if I were to give them here.

Of the difficulties with which the surgeon has to contend in operating on the liver, I would place first and foremost, hemorrhage from the hepatic parenchyma. The question of a proper incision in order to freely expose the tumor is also an important one for consideration, but I believe that in the vast majority of cases one carried along the border of the right rectus muscle will be quite sufficient for extirpation of the gall-bladder alone. An incision carried towards the median line will sometimes facilitate the operation, and in a few cases it may be necessary to resort to Czerny's incision which is made by making an incision in the linear alba and one perpendicular to this just below the umbilicus.

Where resection of the liver is to be done, a longitudinal incision will sometimes be sufficient, but when this is not the case another incision should be made parallel to the costal border, the length of it varying according to circumstances. On account of the complicated condition to which they give rise, I think that the incisions recommended by Micheli and Lannelongue are not to be particularly commended.

As to the control of hemorrhage from the hepatic parenchyma, I think that in many cases it may be avoided if the part is extirpated with the thermocautery with or without the previous application of ligatures in the liver substance. If there is much oozing the stump may be sutured to the abdominal incision and the wound packed with gauze. Other methods for stopping hemorrhage have also been recommended, such as packing the wound with iodoform gauze, or the use of Esmarch's rubber tube. Suture ligatures have also been favorably employed; they are inserted by blunt round needles in the form of chain sutures and by firm and gradual tension they completely close bleeding vessels. This method has of late been highly recommended by Auvray who experimented with this method on human livers removed as soon as possible after death. Langenbuch advised temporary ligation of the portal vein with or without a temporary ligature of the superior and inferior mesenteric artery, but as we

have said in the vast majority of cases resection with the thermocautery will be found sufficient.

The question of the extra- or intraperitoneal treatment of the stump has given rise to much discussion, but personally we would recommend the latter. A comparatively limited number of cases of resection of the liver leaves this question, however, still in the state of study, and it will be only after many more cases have been recorded that we can draw a just conclusion as to this matter.

871 Beacon Street.

THE SUSTAINING TREATMENT OF TYPHOID FEVER, WITH SPECIAL REFERENCE TO THE USE OF HYPNOTICS.

By A. H. BUCKMASTER, M. D.,
OF THE UNIVERSITY OF VIRGINIA.

An orator may change the meaning of his speech by emphasis, and, if we dwell too much on one part of a plan of treatment and too little on another part, we convey a false impression. I think this has been done generally in the text-books. The importance of securing brain-rest in typhoid has not been sufficiently emphasized by writers and, therefore, it is much neglected by practitioners. It is the object of this brief paper to call attention to this omission and also to suggest a systematic plan of procedure.

The treatment of typhoid may be classified under four heads. Under the first are the various plans for the cure of the disease—the curative treatment. Under the second, the plan of treatment which carries the patient along until the forces of the body destroy the cause of the fever, or the poison proves too much for the patient and death results—the sustaining treatment. Under the third head is considered the treatment of the complications. Under the fourth head are the plans for the prevention of the spread of the disease—the prophylactic treatment.

The sustaining treatment, the only form to be considered in this sketch, is sometimes known as the expectant treatment, but I object to the term expectant, because it implies that we wait with folded hands for Nature to do all the work. While we must avoid meddlesome interference, the campaign against typhoid is an active one from the start. To obtain the best results, it must be carefully systematized. An excellent working plan is as follows: (1) Supply the body with material for giving heat, nourishment and energy; (2) put the body in such position that it will use these materials to the best advantage; (3) see that the waste materials are thrown off from the body. The whole of the sustaining treatment may be summed up broadly as follows: Look out for the input, the output, and save the waste. The process has been compared to a steam engine. We must supply it with oxygen, water and coal. We must regulate its workings so that it will not go too fast or too slow. We must see that the bearings are well oiled and dispose of the ashes. To some extent this comparison is applicable, but the laws applying to dead matter will not apply to living organisms.

The Input includes *food, water, air and sunlight.*

Food.—Milk and eggs constitute the mainstay for the typhoid-fever patient. They are complete foods, containing in themselves all that is necessary to support the patient for an indefinite period. A patient will take the whites of six or eight eggs in milk in the twenty-four hours and during the same time he should not take less than one quart of milk. When the milk is not well borne by the stomach we may give it by enema. First, gently wash out the rectum by throwing therein a warm normal salt-solution through a double current catheter. After this a rectal enema of cream, eggs, salt and water may be used. I have used the following formula for many years with great satisfaction: ℞ Well-beaten egg, one; beef peptonoids, one dram; cream, four drams; salt, five or ten grains; water sufficient to make two and a half ounces. This enema should be gently thrown into the rectum as high up as possible. There is the greatest difference in the result when one is gentle and passes it in slowly and when it is carelessly done. One nurse will use the enema without trouble, and another, on the same case, will report that the patient cannot retain it. This nutrient enema given every four hours will in itself sustain a patient for a long time. Theoretically, we should use the foods that are digested in the stomach where there is no ulceration. Practically, we can use any fluid food that will not cause fermentation or irritate the gut.

A common error in the administration of milk is to allow the patient to drink it as he would water. A result of the ingestion of a large quantity of milk taken at one time is the formation of a clot so large that it cannot be readily acted upon by the intestinal juices. A large indigestible bolus is the result. A good way to prevent such an occurrence is to feed the patient a tablespoonful at a time rather than to allow him to drink from a vessel or through a tube. The amount of food and the intervals must be a matter of study in the individual case. The rule is to give as much food as the patient can digest. The danger of giving too much is greater, particularly at the end of the second week, than too little, but we must not forget that patients are sometimes starved to death. Professor Armour had a homely, but convincing way of pointing out the danger of overfeeding. "If," he said, "the patient puts one egg into his stomach, and he can digest but one, he is the better by one egg; but if he takes two eggs and can digest but one, neither is digested and he has two rotten eggs in his stomach.

Water.—This is more important to the patient than food. He may get along with an insufficient amount of food, but he must have more

water than when in health. A gallon of water in twenty-four hours, when the fever is high, is not a large allowance. If the patient cannot take this by the mouth, we must give him normal salt solution by the rectum. I am not sure that the good results obtained by the baths are not due, to some extent, to the amount of water absorbed. The amount of water taken by the patient should be measured, and if it is enough the hard, cracked tongue of the patient will rarely be seen.

Air.—This is the third substance mentioned under the heading input. Its importance has not been properly recognized. We know what it will do in tuberculosis and typhus fever and I do not think any one will oppose the open-air treatment in these diseases. I would like to move all severe cases of typhoid into the open air, with only enough shelter to screen them from the direct rays of the sun, the dew, and the severe winds. There is no danger of a patient with a high temperature taking cold. Of course, the body, under such circumstances, should be kept warm by hot-water bags and light, warm clothing. I am sure that such a plan, carried out with judgment, would lower the mortality a great deal.

Sunlight.—We do not know why sunlight is so necessary to man, but its banishment from the sick chamber, without good reason, is, to say the least, depressing. In this disease we need all the cheer we can obtain.

The Saving of Waste.—We must save the patient all unnecessary wear and tear. We must give him as little work to do as possible; rest for the body and rest for the mind. We must keep him quiet, making him use the bedpan and teaching him to avoid all sudden and jerky movements of the body. It is not desirable for him to lie constantly on the back, and he must cautiously turn on his side from time to time with the aid of the nurse. It is usual to secure rest for the body, but rest for the brain is often forgotten. In the condition known as *coma vigil*, the patient lies with eyes half open and muttering in a low voice. What is the brain doing during this time? If we may judge from the incoherent mutterings, it is flying from subject to subject and probably does an enormous amount of work in a short time. The patient is attempting to climb impossible heights and is falling into bottomless depths. Days and weeks are compressed into hours. It would take a pen more facile than that of Dickens to follow the mental wanderings of such a patient. The great writer attempted this in Martin Chuzzlewit and, although he gives us a wonderful picture, it falls far short of reality.

The man who relies on the report of a nurse to find out how much the patient has slept will often be deceived. If the patient does not call for some service, between the times for the administration of food or medicine, she dozes uneasily in her chair and reports the next morning that the patient was quiet; and yet a short period of such quietness will wear the patient out. He is not sleeping. His brain, instead of getting rest, is in a state of activity and unless the doctor or Nature changes the condition of affairs, the patient will die. We think much of the food the patient is taking; we think a great deal of the waste from high temperature; some of us are solicitous to give enough water, but how many men have the period of true sleep measured every twenty-four hours? Man bears the loss of food much better than the loss of sleep. I do not know of any attempt to find out how much rest is necessary.

This paper is a plea for the measurement of the period of true sleep in the twenty-four hours. If the patient will not sleep naturally he must be made to sleep by artificial means. The bath will produce sleep, but it does not last long. It is valuable in initiating the effect of a hypnotic which would be ineffectual without its aid. The hypnotic which has given me the best results is sulphonal. I believe that it is usually given in too small doses. One should commence with fifteen grains and if this is not effective, increase the dose to a dram in some cases. It usually takes about five hours to act thoroughly. Trional in ten-grain doses will do good work. Its effect is somewhat quicker than that of sulphonal; about three hours is the average time. Chloral is very useful. This drug went out of general use, because it occasioned several deaths, but the late Dr. Squibb told me that he felt quite sure the ill results were due to an impure article. From fifteen to forty grains will put the patient to sleep. These doses may seem large, but the need may be urgent. The patient should be watched after the administration of large doses of a hypnotic and, if the heart gets very weak, stimulants must be used. If the stimulant is given too soon, the effect of the hypnotic will be lost. This is a common mistake. If the time for the administration of stimulants, in the routine treatment, comes at the time sleep is looked for, it must be deferred. Of course if the arterial tension is very low, we may induce sleep by the use of a stimulant. The use of hypnotics is a matter of considerable skill. I do not believe that the bromides in small single doses are of any service. When I was substituting, many years ago, at the Brooklyn Hospital, it was the custom to give twenty or thirty grains of bromide of potassium as a sleeping-draught. The solution was kept in a gallon bottle. Being a little skeptical as to the efficacy of this medicine in the way it was used, I poured it out, without saying anything to the nurses, and substituted enough common salt to give the mixture a strong saline taste. I watched the night nurse's reports for several weeks after this and, comparing it with the reports of the weeks previous to the change, found that the salt solution was quite as efficacious as the bromide.

Morphine is a valuable hypnotic, but it locks up the secretions of the liver and at times nauseates the patient. Again, if the dose is too small,

it stimulates and excites the patient, instead of calming him. If it is given by the needle, it makes trouble for the doctor, for a nurse should not be allowed to give a hypodermic injection as a routine of practice or at any time except in a case of emergency.

There is no question that careful management of the fever will aid materially in the saving of waste. A fever too long continued, if it is sufficiently high, will kill the patient, but I am inclined to believe, on clinical grounds, that we have been too meddlesome in the past. I have given up the use of all the coal-tar antipyretics. They depress too much. The safest way of reducing the temperature is the abstraction of heat by immersing the patient in a bath, which may be made as cold as it is consistent with comfort. The cold baths of Brand are brutal and, personally, I think I would rather be permitted to die than go through what I have seen patients suffer in their use. Again it is strange to learn how many nurses can tell you of patients that have died in, or immediately after, the baths, particularly in the case of children. The ice-cap and the abdominal coil are useful at times. The interesting experiment of Pasteur, who found he had to reduce the temperature of a fowl before he could inoculate it with anthrax, is something to set us thinking. I have no doubt that with increased knowledge, we shall be better able to judge when to interfere with temperature and when to let it alone. I confess that I do not feel much alarmed if the temperature goes up to 106° or 107° F., provided it does not stay there too long. Of course, the bath does a great deal in addition to the reduction of temperature, but I think we can get its best effects without torturing the patient.

After the second week, alcohol is of the greatest service. It must be given in the proper amount and this can be determined only by experiment. If the restlessness increases after its administration, if the odor is detected in the breath and if the pulse becomes accelerated, the amount must be decreased. If, on the other hand, there is improvement of these symptoms, it may be pushed until the condition of the patient is satisfactory and all this irrespective of the amount, which may vary from a few ounces to a few pints in the twenty-four hours.

When we can no longer use strychnine with good effect; when we wish a greater stimulating effect than can be obtained from alcohol, there is nothing that will give as good results as the intravenous injection of about a quart of the normal salt solution. I have seen the pulse drop from 135 to 98 in three hours after a transfusion of forty ounces. The patient, who before the injection had been rolling about in an uneasy way in the bed, settled down into a quiet sleep. Whether the dilution of the poison had anything to do with this result I do not know, but the effect was decided and very satisfactory.

The Output or Waste Material.—Waste material is thrown off by the bowels, the kidneys, the skin, and the lungs. We do not know how far one organ can act for another. The bowels may help the kidneys, but each organ must do a certain amount of work and all should be watched. It seems to me that the cases with two or three movements of the bowels each day do the best, and if a patient does not have at least one free movement in the twenty-four hours, laxatives or enemas should be used. An occasional dose of calomel is of great service. I have given up trying to secure aseptic stools and I am not sure that the food would be well digested if such a thing could be done. At the same time, we must not leave a lot of poisonous fluid material in a gut that is sluggish in its movement. Few do not recognize the futility of trying to sweep out the bacillus of Eberth from the intestines, for it is in the wall of the gut, in the blood, in the lymph-structures, in the spleen, in the bone marrow, etc. If there are more than two copious movements, a slight astringent—strong tea does very well—will usually afford relief. It is good practice to use a stimulant after the movements.

In regard to the work of the kidneys, it helps us to know the amount of urine passed. The trouble of collecting the urine is considerable and for this reason it is not done oftener. We must also know the character of the stools.

At least half the cases of typhoid at one time or another have albumin in their urine. This usually means that the blood-pressure is too low or that the intestine needs cleaning out. An increase of stimulant or an efficient dose of calomel will usually cause the albumin to disappear. If it persists under such conditions, we have reason to be apprehensive of organic changes in the renal epithelium.

If the skin is inactive, the use of a hot pack will be of service. In the first week it will sometimes bring out the eruption. I have seen brought out in this way a characteristic typhoid eruption that was as profuse as those we sometimes see in children. We do not see as much of the sudaminal eruption as formerly, because of the frequent bathing of the skin. If the patient takes enough water, the amount of urine will usually be sufficient.

The importance of the systematic investigation of the input, the output and the saving of waste cannot be overestimated. We are dealing with patients whose reflexes are often weakened to such an extent that they are far more helpless than a baby. In the first stages of the disease they are indifferent and apathetic; later on they become dull. At first they know, but do not care; then they do not know except under unusual conditions; at a later stage they do not know under any conditions. Such patients will remain with enormously dilated bladders without making any sign.

To sum up the sustaining treatment of typhoid fever:

(1) *No practitioner has done his duty who does not know at the end of each twenty-four hours that the patient has had enough food, water and fresh air.*

(2) *No practitioner has done his duty who has allowed the patient to wear himself out by continued high temperature or by lack of sleep. The amount of sleep in the twenty-four hours should be recorded.*

(3) *No practitioner has done his duty who has not examined the urine frequently, and who has not posted himself daily as to the condition of the urine, the movements of the bowels and the condition of the skin.*

CLINICAL MEMORANDA.

COMPOUND DISLOCATION OF THE KNEE.

By WALTER LATHROP, M.D.,
of Hazleton, Pa.;
Superintendent and Surgeon-in-Chief, State Hospital, Hazleton.

This injury is so infrequent that the following case is deemed worthy of reporting. In looking up literature on the subject I find the cases of *compound* dislocation very rare; in fact, text-books dismiss the subject with few words, although the American Text-book of Surgery states that "the dislocation is frequently compound." The severity of my case, however, could not bring it under the head of frequent. Of course, a forward or backward dislocation of the tibia, accompanied by a wound, no matter how small, would be compound; such may be comparatively frequent.

B. D., thirty years of age, while at work in the mines January 19th, saw a car off the track and went to assist those engaged in replacing it. To use his own words, "The end car was off the track, and I was by the side of car next to end, when the engine started the train, and the car was lifted up and fell over on me." It was some time before he was extracted. He was placed on train and brought to hospital as soon as possible.

Examination showed a bad fracture of the left femur at the condyles, while the right femur was protruding at the *under side of knee*, completely denuded of tissue, the condyles, and articular surfaces being stripped clean. Popliteal artery was ruptured. The wound of exit was not large, but the bone had been forced through by the enormous pressure of the loaded car, which pinned him against the props of the mine. Shock was severe, but after some time reaction was established; he was then anesthetized and I amputated the limb just above the seat of injury. He reacted well and is now doing nicely.

One year ago, I had a case of compound dislocation of the right humerus, the head being driven through the pectoral muscles, close to the clavicle. This was reduced and attempts were made to save the joint, but these resulted in an excision. The patient recovered and has a very useful arm.

Grip in Copenhagen.—There were 1,700 cases of influenza reported last week. Several deaths occurred from the disease. In general, however, the epidemic in Europe, is similar to that in this country, in that the disease is rather mild.

NASAL OBSTRUCTION; MOUTH BREATHING; CATARRH; DILATORS.

By NORBURNE B. JENKINS, M.D.,
of Chicago.

The most common troubles which reduce the size of the nasal passages are cartilaginous growths, bony growths, deflections, deviation and deformity of the bones and cartilage forming the nasal cavities, hypertrophy and edema of the lining membrane of the nose, polypi, enlarged turbinated bodies, discharges from inflammation and disease of the nasal mucus membrane, stenosis, arrested development, atrophy, discharge from dead tissue, discharge from disease of the air-cavities or sinuses communicating with the nose.

The chief causes in the production and development of obstruction are as follows: Not using the nose in breathing, general hypertrophy, constitutional taint of disease, injuries from external violence, infection, irritation by such foreign bodies as dust, etc.

The upper air-passages warm, moisten and regulate, and free from foreign particles the air passing to the lungs. Any long-continued interference with this important function is followed by disease. If the volume, pressure or presence of air in the nose is not normal, growths, deflection and other diseases are invited and the nose may become closed. Arrested development, atrophy, hypertrophy, growths, polypi, stenosis, deflection and deformity, can and often do result simply from not using the nose in breathing.

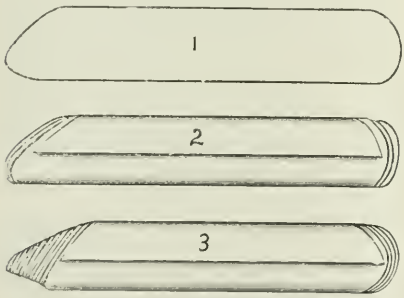
Mouth-breathing quickly becomes a habit. Even after obstruction is removed, the nose may not be used in breathing and consequently becomes obstructed again. If the nose is temporarily stopped up, the mouth for the time, must be used in breathing. In these cases mouth-breathing may continue from habit, even after the nose is open.

The surgeon who is familiar with the anatomy and pathology of these parts finds little difficulty in relieving most obstructions, yet treatment of sinus diseases and necrosis often requires great patience and skill. The laity wisely call these "incurable catarrh." If there is long-standing, yellowish discharge, dead bone or disease of one or more of the numerous air-cavities or sinuses may be suspected. The discharge may come from one or both nostrils.

Diagnosis and treatment of disease in the sinus of the upper jaw-bone is comparatively simple. In the small accessory sinuses it is often difficult or almost impossible to locate the source of discharge, and, notwithstanding simple methods given in text-books for diagnosticating and treating, the operator may have the chagrin of finding, after weeks and months, that the discharge is not controlled, nor its source even located. These troubles are usually curable, therefore the more exasperating. The reader will find in the text-books information more definite and detailed.

Many non-discharging obstructions may be treated with constant pressure. This is probably best made with folded writing-paper dilators, in size about one-half-inch by two or three inches. The illustrations are somewhat enlarged. At first the dilators should be the thickness of three or four sheets of paper. In many cases of occlusion and stenosis a dilator cut from best visiting-card board is easily introduced and useful. As the nose opens, thicker and later, wedge-shaped ones are used, thus conforming to the shape of the normal nose. The entire length of the dilator should rest on the floor of the nose, and it should be sufficiently far inside the nostril not to show.

Spray the nose with a two-per-cent. solution of cocaine, anoint the dilator with iodoform ointment or petrolatum and introduce with forceps. Remove after a day or two and replace with a new one. No harm has resulted from wearing a dilator a week without changing, but this is not recommended. Hasten slowly, use



Nasal Dilators.

thin ones first, and gradually and painlessly pass to thick ones. In occlusion and stenosis, a passage for the dilator must sometimes be made with a thin saw, and in such a case one size or another should always be in the nose until completely healed.

In case of trouble in introducing, the dilator may be made like a scabbard and put in place with any long, thin, springy instrument. The dilators are not often indicated in people past middle age. If the nose is sufficiently open, or has been made so by knife or dilator, and the patient breathes through the mouth, a bridle, described in the *Medical Record*, September 10th, 1898, may benefit, if worn during sleep. The bridle is a reminder to the patient and is not to lock the jaws. In many mouth-breathers, the muscles which hold the jaws closed may become atonic and may need the assistance of the bridle in overcoming the habit.

Diseases of the respiratory tract can not be successfully treated if there is persistent mouth-breathing. In some diseases of the ear the habit interferes with recovery. In treating disease of the air-passages too much dependence is placed on atomizers and insufflators and not enough on physical hygiene. Many stubborn cases of hypertrophic rhinitis, middle-ear catarrh, tonsillitis, "bad colds," and arrested development, may yield to hygienic measures without other treatment.

MEDICAL PROGRESS.

Every-day Headaches.—These may be considered, writes Hugh T. Patrick (*Medicine*, Jan., 1901), due to infection and toxemia from fever, Bright's disease, constipation, etc., to neurasthenia, to migraine, to eye-strain, or to anemia. The obscure ones are the head pains of neurasthenia and migraine. The former is not a severe pain, but an intense distress or discomfort, a sense of pressure, or constriction, or expansion, of heaviness, lightness, fulness, or emptiness, or of a foreign body, solid or liquid, loose or fixed, within the cranium. Frequently there is a feeling of hindrance to mental effort. A pain located in points, lines, squares, circles, etc., is neurasthenic. Not infrequently there is a dull ache behind or over the eyes, and a sensation of bulging or pressure in the orbits not relieved by glasses. The headache may disappear during social intercourse or absorbing business, to reappear at the next opportunity for undisturbed self-contemplation. A headache which continues for months is pretty sure to be due to neurasthenia or to grave organic disease. The only cure is that for neurasthenia, but palliative treatment by strychnine, or 20- to 40-grain doses of bromide may be necessary. Migraine appears in distinct attacks separated by entirely free intervals, but during the attack the pain is constant and severe and usually prostrates the patient. It is deep-seated, although the scalp may be tender. It is usually hereditary and begins before the twentieth year. The attacks last from six to thirty-six hours and occur at first two or three times a year; later as often as twice a week. Nausea or vomiting is rather frequent; there is often a definite prodrome, and during the attack sleep is impossible. An attack may be precipitated by pain, loss of sleep, mental strain, etc. Women not infrequently lose the affliction after the menopause and men after the age of sixty. The author's treatment consists in the administration of fluid extract of cannabis indica, three drops after each meal, increased rapidly to the physiological limit and kept there. If this fails, try bromide or nitroglycerin, or a mixture of sodium salicylate, sodium bromide and aconitine.

Retropharyngeal Abscess.—Though rare, writes Irving M. Snow (*Arch. of Pediatrics*, Jan., 1901), this is one of the grave affections of infancy, and is commonly treated as pharyngitis or croup. The baby will attempt to nurse and

will quickly drop the nipple and cry; or it will refuse all nourishment. If the abscess is in the upper pharynx the cry is nasal, the breathing snoring and snuffling, and the child sleeps with the mouth open. If at the level of epiglottis or larynx, there is hoarseness, stertorous breathing, and attacks of choking or cyanosis, all symptoms are aggravated in the recumbent position. Usually the neck is swollen, the cervical or submaxillary lymph-nodes enlarged, with fever and constitutional disturbance. With such symptoms the throat should be palpated, and no time should be lost in evacuating the abscess.

Bacteriology of Gastro-enteritis in Infants.—The importance of bacterial studies in disorders of the gastro-intestinal canal in infants is so universally recognized that this was a question of the day at the recent Congress in Paris. Among those who participated in the discussions none has contributed more to the subject than Escherich of Graz. Summarizing his results of extended studies in this direction in a short paper (*Arch. de Méd. des Enfants,* Dec., 1900) Escherich reaches the following conclusions. (1) The use of Weigert's fibrin stain and fuchsin with feces gives useful results, enabling one to differentiate the bacteria found in the stools of breast-fed children, and the colon bacillus which decolorizes by Gram. The inoculation of ordinary alkaline media (agar and gelatin in plates) succeeds only to a limited extent in demonstrating the bacteria observed in cover-slip preparations. By employing certain acid media it has been observed that the normal intestinal flora is still greater than had hitherto been suspected. The use of the Grüber-Widal reaction enables the differentiation of closely-allied forms of the colon group found in the alimentary canal. (2) The normal intestinal flora is the expression of the conditions of the normal function of the intestine. (3) The bacterial flora, under normal conditions is independent, in a large measure, of the variety and number of bacteria introduced with the food. At all events, small disturbances in the chemistry of the intestine, of secretion and absorption, of the general health and powers of resistance, affect the bacterial flora very markedly. (4) For many reasons it may be assumed that the introduction and multiplication of any micro-organism not common to the normal flora may induce morbid changes. This may occur through unusual ways of decomposition resulting in the formation of poisonous substances. (5) At the present time there exists no satisfactory classification of the gastro-enterides of infants. From a bacterial standpoint three types of infection are recognized: (*a*) Intoxications through ectogenous decomposition; (*b*) infection of the chyme; (*c*) infection of the intestine. (6) The number and kind of bacteria present are important factors in the pathogenesis of these infections. (7) The belief that the death-rate from gastro-enterides progressively diminishes in infancy as age advances is not in accordance with the author's personal and very extensive experience.

Post-Operative Ventral Hernia. — B. B. Eades (*Annals of Surgery,* Jan., 1901) says that at least fifteen per cent. of all laparotomies are productive of herniæ after a lapse of five years. Many surgeons fail to see these results in their own cases, because so many patients seek the aid of other operators for these unfortunate outcomes. Hitherto only the physiology of the parietes, but now the anatomy also has necessarily to be considered, because it alone will aid in the reconstruction of the walls so as to prevent hernia immediately and remotely. He recommends that the incision through the skin and fascia should be at an angle to the direction of the muscle fibers and nerves, as great as possible. Only innervated muscle will functionate and prevent visceral protrusion, hence the greatest possible respect must be had for the nerve and the muscle and sharp division of either or both avoided to the last moment. The general rules for the parietal cut he formulates as follows: (1) Length depends upon the thickness of the superficial fascia, always enough to give wide access to the muscles; (2) relatively greater length when separation, not division, of the muscle fiber is to be done; (3) always proportional to the suspected pathological conditions; (4) with view to rapidity, dexterity and precision of deep field work; (5) long incisions in the skin and fascia do not predispose to hernia; (6) lessen the mortality by increasing space for protecting the surrounding viscera; (7) decrease shock by shortening the time. For appendicitis he transposes the intramuscular incision of McBurney downward, so that it is centered on a line joining the anterior superior iliac spines and from one to one and a half inches internal to the right This almost invariably brings into view the iliohypogastric and ilio-inguinal nerves, so that they may be protected and spared, and also opens the parieties just below the pouch of the cecum.

Hemorrhoids.—The treatment of these very common and vexatious conditions, says Quenu (*Gazette de Gynecol.,* Jan. 1, 1901), depends largely upon the causes and degree of the disease. Dilatation of the anus tends to restore the venous circulation and to obviate some of the complications which are associated with really descended piles. For the actual destruction of these venous tumors one may employ any of the well-known radical procedures, clamp and cautery, ligature, galvanism, bistoury or scissors. For a slower removal of them various means are employed at the periphery and at the center of the tumor, such as painting the surface, cauterizing, electrolysis, and interstitial injections. Normal living and regulation of defecation are important. Daily baths or at least local washing of the anorectal skin and mucosa are splendid preventives of infection and abscess. In the presence of the actual piles cold or very hot (40° to 45° C.) applications and irrigations, also hot sitting-baths with or without astringents added, like sulphate of zinc, alum, tannin, etc., suppositories of these or of subnitrate of bismuth, or galvano-electric stimulation or cauterization are very good. Inflammation

demands cold, heat, poultices, exhibition of calomel, ointment with morphine or cocaine and, finally, the knife, if these means fail. Since mere dilatation does not prevent recurrences and may promote prolapse, to-day radical cure is preferred. Hartmann in the absence of inflammation removes them through a flap-formation, uniting the edges with fine silk afterward, in the presence of inflammation he omits the suture, packs the rectum with gauze to appose the cut surfaces and finds cure present in about seven days as a rule. Quénu and Hartmann have modified the Whitehead operation as follows: The anus is circumscribed with an incision at the mucocutaneous juncture for half of its extent, the mucosa with the piles adherent is dissected free and everted upon the finger; the piles are now ablated, the bleeding is checked, and then packing of the rectum to hold the flap in place finishes the procedure, after the other half has been similarly treated. The typical Whitehead operation is necessary when the mucosa is much altered. All operations must be preceded by moderate dilatation of the anus.

Abdominal Hysterectomy.—G. Nanu (*La Gynecol.*, Dec. 15, 1900) gives the following leading points for this operation: A 45° Trendelenburg position from beginning to end, until the parietal suture begins; a large retractor held at the lower limit of the wound by an assistant standing between the feet of the patient, who shifts it from side to side, always over the point of operation; systematic abandoning of the hemostatic forceps on large vessels, ligating at once instead; ligation of the hypogastric arteries. The foregoing points assist in rapidity and the following in asepsis: Abandonment of all chemical disinfectants, using only heat for sterilizing; careful walling-off of the peritoneum; reconstruction of the peritoneal layer on the pelvic floor; all ligatures of catgut; all sutures of the same substance, except at the skin, where silkworm gut is used. As to the comparison between this and the vaginal route, he thinks the abdominal the more truly surgical, because it is rapid, free and complete in its work.

Removal of the Seminal Vesicles.—H. H. Young (*Archiv. f. klin. Chirurgie*, B. 62, H. 3) states that of all the avenues of approach to these organs usually adopted the three mentioned as best are the perineal, inguinal and sacral. The sacral route is the most advantageous to the surgeon for view, but is difficult and prolongs the operation considerably. A new route is suggested by the author, the suprapubic, and has the following technic: A median incision is made from umbilicus to symphysis. If this does not give sufficient exposure there may be made an adjunct incision vertical to it either through the recti abdominis muscles just above the symphysis or better through the linea semilunaris just above the umbilicus. The second-named site for this additional cut is by far the better, because it does not injure muscle fibers, gives no paralysis and much less tendency to hernia. The deep field is extraperitoneal if possible. The bladder is freed from its bed and drawn upward and forward over the symphysis and held. With it comes the prostrate and the seminal vesicles. These are then dissected free of their attachments and with them the ampulla and course of the vasa deferentia. If castration has been done, the whole vas and vescicle of that side can be removed. The advantages of this method are completeness, comparative rapidity, directness and the safety of any ordinary laparotomy.

THERAPEUTIC HINTS.

Hot Air Treatment.—The apparatus used at the Royal Victoria Hospital, write C. F. Martin and B. D. Gillies (*Montreal Medical Journal*, Dec., 1900) consists of a copper cylinder large enough to admit an extremity, the pelvis, or the whole trunk, and with a thermometer and valves to allow the air to circulate. The part to be treated is wrapped in flannel, is placed on an asbestos cushion in the cylinder, and rubber sheeting is wrapped about it. The temperature is gradually raised from 180° to 260° F., then rapidly to 280° or 300° F. or more. The patient drinks freely of water. In the cases of gonorrheal arthritis the pain was relieved, the mobility increased, the effusion absorbed, and walking rendered more quickly possible than by any other means tried. This was the result in other painful effusions and acute or subacute joint affections, while in arthritis deformans and chronic rheumatism the effects were less lasting. Besides joint affections, cases of peripheral neuritis, local neuralgias, and sciatica (29 cases) were relieved with astonishing rapidity.

Fatty Heart.—In ordinary cases, writes W. H. Broadbent, the food should be liberal and varied, precautions being taken against inordinate or injudicious eating. It is best to have someone who understands the likes and dislikes of the patient determine what dishes and what quantity will be good, acting under the physician's advice. Proper regulation of the bowels is of the utmost importance. The quantity of feces which may unconsciously accumulate in the bowels of old people in spite of a daily slight evacuation is astonishing. Such may induce complete prostration, which may last for months, or result in fatal syncope; or there may be cerebral symptoms, and complete loss of memory, with childishness and torpor. To regulate the bowels mild aloetic aperients are best, with pil. hydrarg. and colocynth occasionally if there is arterial tension. Any tendency to flatulent distension of the stomach must be counteracted by careful dieting, and by alkalies and carminatives. Bitter tonics, massage and gentle exercise are often of great service. Extremes of heat and cold should be avoided, and a dry healthy country spot selected for residence.—*Heart Disease.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

INHUMANITY AND THE HUMANE ASSOCIATION.

Nowhere is one so forcibly reminded of Landseer's famous picture of "Dignity and Impudence" as when the human traits that the picture caricatures are portrayed in some calm, large-minded scientific man, and a cocky, self-sufficient gentleman with a chip on his shoulder.

From advance sheets of the *Journal of the American Medical Association,* we read with interest and amusement a discussion in which Dr. W. W. Keen calmly lays down the law to the president of the American Humane Association in this gentleman's own terms. The trouble is *apropos* of the Bill for the Regulation of Vivisection, and the text is Dr. Keen's published statement to Senator Gallagher that in a pamphlet issued by this Association the experiments quoted were "many of them so vague and indefinite that he could not look them up," and that some of those he did find were "garbled and inaccurate."

We grieve to say that the worthy president of what was supposed to be a respectable society feels it his duty to "probe and investigate this charge to the fullest extent," and incidentally hints that Dr. Keen's remarks are "not quite in accordance with the highest ideals of truth," and concludes his remarks by intimating that there is need of enlightenment "if the medical profession of this country is ignorant of what has been done by men without pity and without conscience." To all of which Dr. Keen, from whom he has pompously demanded proof, furnishes what he asks.

The Humane Association had caused to be distributed from house to house in Washington, prior to the reading of the Bill, a pamphlet in which were reported a number of experiments, fourteen of which were drawn from newspaper stories. Dr. Keen points out that five of these cannot be consulted for lack of date, and adds that in no case would he be willing to admit a newspaper paragraph as a sufficient authority for a grave charge against an individual or the profession. He then quotes six other "vague and indefinite" references, not to newspapers, in which dates are omitted or incorrectly given, so that there is no possibility of verifying them.

As to Dr. Keen's defence of his words that "some of the statements were garbled and inaccurate," which so rankle the humane gentlemen, he gives a series of cases in the pamphlet in which it is reported that doses of thyroid gland were administered to insane patients—and the patient died. No mention is made of the actual cause of death which were given in every case in the official report from which these "garbled" sentences are taken, neither is there any mention of the cases that were greatly improved. In the same way, Dr. Keen supplies the omissions which his opponent sarcastically demands by stating that in five experiments of lumbar puncture made by Dr. Wentworth, the pamphlet simply records the fact that a lumbar puncture was made and the patient died a certain number of days afterward. The omissions are Dr. Wentworth's express statement that "no reaction on the part of the patient attended the operations," and that autopsy showed the cause of death to be "inflammation of the brain," "galloping consumption," "double pneumonia," etc.

In reporting on Sanarelli's experiments in the inoculation of yellow fever, the account is "garbled" by inserting in the symptoms the word "final," *i. e.,* "jaundice, delirium and *the final collapse,*" which does not occur in the original. The last three words are italicized in the Humane Association's report, leaving the impression that the patients died, whereas Sanarelli states *that not one of them died.* Notwithstanding Sanarelli's statement, which the compiler of the report must have read, he quotes from the *Boston Transcript,* "It is understood that some, if not all of the persons

inoculated died of the disease," and the words "scientific assassination," "death" and "murder" are freely quoted.

The "garbling" of a translation of Schreiber's inoculation of a boy with tuberculin, which in reality was for the sake of early diagnosis, is shameful, it being insinuated that the physician did it simply to see whether the boy could be inoculated with the disease. The physician's final report is: "I could discover no other alterations in the otherwise apparently healthy boy." It is rendered "I cannot yet say whether the boy will be consumptive in consequence of my treatment."

The confident tone of outraged humanity with which Dr. Keen was called upon to deny the profession's responsibility, if he dared, will, we hope, assume something like apology when the gentleman finds out what manner of man he has been calling out to battle. For it is not a fight over calling names, but the same fight for humanity against a sentimentality and scandalous misrepresentation that vaccination, anesthesia, antitoxin and every great discovery in medicine have had to make.

MALARIAL PROPHYLAXIS IN NEW YORK.

We reviewed in these columns in a recent issue, January 12th, the interesting chapter of the evolution of the theory that the mosquito carries malaria. This subject has been brought so much to the notice of the profession during this last year or two that now a headline reference to it is apt to be greeted by a yawn. Outside the tropics medical men are prone to think that it is of passing, even surpassing, interest because of the original wondrous intuition of the theory and the ingenious demonstration of it from so many sources, but practical importance it can have none except in distinctly malarial countries. It is forgotten, for instance, that there is and has always been a distinct mortality from malaria in and around New York City. This has decreased very much in recent years, but has not disappeared. One reason for the decrease has been the evolution of exacter diagnosis. This factor will undoubtedly still further lessen the number of malaria cases in the city during the next few years. No diagnosis of malaria should be made unless the parasites have actually been seen in the patient's blood.

The second factor in the decrease of New York's malaria is the gradual obliteration of suitable breeding-grounds for the mosquito. In this line there remain opportunities for the further reduction of malarial mortality and morbidity in the neighborhood of the city. At the last meeting of the American Medical Association two observers recorded the finding of the *Anopheles* mosquito in our Northern States during the winter. In Boston during December and January, in Philadelphia during November and February, specimens of the malaria-bearing mosquito were found. The insects were observed in barns and outhouses, never far from some abundant water-supply and usually in the neighborhood of some animal, a dog or a horse or cow. In Italy attention has been called to the fact that mosquitoes hibernate. Only the impregnated females survive the winter it is said.

At the recent meeting of the Section on Medicine of the New York Academy of Medicine Dr. W. N. Berkeley called attention to two interesting sets of facts. First, the conveyance of malaria from person to person in New York and, second, the regulations that would greatly facilitate the ultimate extermination of the disease. The *Anopheles* mosquito Dr. Berkeley has found in most of New York's suburbs. Visitors even only for a day or two to these suburbs, who happen to be stung by the insects, not infrequently contract the disease and it has been possible to trace the exact length of the incubation period of malaria by knowing the date of the suburban visit.

So long as the present system of extending the streets of New York continues we cannot hope for absolute freedom from malaria. Streets are raised to grade by the city and owners are left to fill in their property at their convenience usually years afterward. This leaves stagnant ponds of water that make ideally favorable breeding-places for the *Anopheles*. Until these low-lying vacant lots and all other standing puddles of water can be filled up and drained, it is almost hopeless to expect a reduction in the number of mosquitoes. Where the mosquitoes are, malaria will be distributed, if a single case of the disease finds its way to the neighborhood.

In the country places around New York City much can be done by at once protecting all malaria patients from being stung by mosquitoes. *Anopheles* to convey malaria must be freshly reinfected every spring. In the spring especially relapses of old malaria occur. From these relapsing cases the mosquitoes get their supply of infective material. If malaria patients are protected from mosquitoes, by no means an impossible precaution, as has been shown in

Italy where the insect pests are much more abundant than in this country, there will not be any distribution of the disease beyond its original focus. There is absolutely no other intermediary for the conveyance of malaria from man to man except the *Anopheles* mosquito.

If, in addition to this, all standing water is either drained off or kept covered during the spring by a thick layer of crude petroleum, then the opportunities for the spread of malaria are minimized and cases of the disease must become infrequent. If these two measures, the shutting in of malaria patients and the drainage of stagnant water were instituted by legal regulation, just as is the quarantine of other contagious diseases and the abatement of nuisances, we would soon hear the last of malaria around New York. As it is, the public should be educated up to our present knowledge of the status of malaria as a mosquito disease. A set of instructions printed with the authority of the health boards of our Northern cities and distributed among dwellers in suburbs where malaria still occurs, would undoubtedly lead to a better enforcement of the simple precautions necessary to prevent the spread of the disease. For us even more than tropical countries the mosquito-theory of malaria is of practical importance. To neglect its obvious lessons is to miss valuable opportunities for the decrease of human suffering.

DISINFECTION OF THE HANDS.

Of late there has been an unusual degree of interest in the study of different methods of disinfection of the hands. The importance of such disinfection is now thoroughly recognized, and laboratory and other means of determining the best methods of disinfection have been greatly multiplied since the days when Lord Lister introduced antiseptic surgery. There has been a tendency to insist more and more upon the importance of mechanical disinfection of the hands, as compared with the chemical disinfection which was formerly considered most important. Schleich of Berlin has been particularly impressed with the importance of such mechanical disinfection and he has recorded some very satisfactory results.

Among several careful experimental studies which have been recently undertaken to try to solve this important question, that of Krönig and Blumberg (*Beiträge zur Händedesinfektion,* Leipzig, Georgi, 1900), deserves careful reading. These writers have carried out an extensive series of experiments in which they have inoculated over eight hundred mice, besides making numerous culture tests. Because of the dangers of infection with the anthrax bacillus, which is so resistant to ordinary means of sterilization, they used the skin of cadavers for experimental purposes, rubbing the bacilli into the skin, allowing it to dry for a considerable length of time and then carrying out the various methods of disinfection. After purely mechanical disinfection of the skin by means of soap and water applied with a brush and marble-dust, as recommended by Schleich, they cut out bits of skin by means of sterilized scissors and forceps and inserted these bits into subcutaneous pockets in the skin of mice. By this method of disinfection the skin was so thoroughly freed of germs that only a few of the animals died of infection. However, the method was by no means perfect. Cultures on agar plates also showed colonies of anthrax in a number of cases. They next tried the use of tincture of soap and alcohol, as first recommended by Reinicke, a method which has been widely used by German surgeons and is particularly favored by Mikulicz. This may be considered the next step toward chemical disinfection. The results were very much the same as with the soap, water, brush and marble-dust method, experiments both by inoculation of mice and cultural experiments showing that we can only partially free the skin of germs by mechanical means even if combined with alcohol.

As previous investigations had shown that these methods were not effectual, Krönig and Blumberg did not carry out an extensive series of experiments with this method. Further experiments were carried out, using mechanical disinfection in combination with chemical disinfection by a mixture of permanganate of potassium with common salt, thus setting free chlorine, which acts as a powerful disinfectant in the nascent state. The results by this method were decidedly more satisfactory, and the writers conclude that the combination of chemical disinfection with mechanical disinfection is decidedly to be preferred, though they believe that the thorough mechanical disinfection of recent times is a decided advance.

Although it can thus be shown experimentally that disinfection of the hands is possible, there can be no question that in some cases any of the ordinary methods which have been used are not effectual, either because not carefully carried out or from the condition of the hands of the surgeon

at the time. There is always the possibility that in certain cases, through hurry or neglect, the ordinary methods will not prove absolutely certain. These experiments and others only show that in order to be sure that we are not carrying infection into a wound we must cover the hands with some impermeable material. Whether this can be best accomplished by the use of rubber gloves, which are now most extensively used, by the use of leather gloves permeated with some substance preventing skin bacteria from passing through, as recommended by Wölfler of Prag, or by covering the hands with chirol or some other form of shellac, remains to be shown by further trial. All of these methods blunt the touch and hinder skilful manipulation in some degree, but the assurance of perfect asepsis makes it well worth while to put up with some disadvantages.

ECHOES AND NEWS.

NEW YORK.

Appointment of Dr. Marston.—Dr. Daniel W. Marston has been appointed Visiting Surgeon to the Randall's Island Hospitals, by the Department of Public Charities.

Gift to Yale Medical College.—One hundred thousand dollars was recently given to Yale University to construct a building for the medical school. The donor's name was not made public.

Influenza Epidemic.—The reports from the Marine Hospital Service indicate that influenza has been epidemic over the entire United States. The Western States were apparently invaded at about the same time as those of the East. The disease first made its appearance in most States in December, has been mild in character, for the most part, and has declined somewhat under the influence of the cold weather.

Diamonds for a Diploma.—In the exchange column of an evening paper there appeared, a few days ago, the advertisement of one who was willing to exchange diamonds for a medical diploma from a well-known college. The only stipulation was that the original owner must be deceased. It would be interesting to know how many were offered, and whether he gave up his precious stones for a sheepskin prepared especially for him by some smarter swindler.

Anti-Christian Science Bill.—The Assembly Public Health Committee will report for amendment and recommitment Assemblyman Bell's Anti-Christian Science Bill this week. The bill will be amended so as to affect only faith curists, and make all persons who pretend to be healers and cure the sick and injured pass an examination before the State Board of Regents, showing their competency in caring for the sick, and their knowledge of disease, by requiring practical diagnosis.

Lectures on Protozoa.—In the lectures on Protozoa to be given by Dr. Gary N. Calkins, that to be delivered on March 1st will be of special interest to physicians. In it the more common disease-producing parasites are to be considered. Gregarines and Diseases of the Earth Worm; Coccidia and Liver Diseases of the Rabbit; Myxosporidia and Trout Epidemics; the Relations of Mosquitoes to Malaria, and Remedies are the subtitles to be discussed by the lecturer. The lecture will be held at 5 p. m. in Schermerhorn Hall, Columbia University.

Mothers' and Babies' Hospital.—At a meeting ing of directors and friends of the Mothers' and Babies' Hospital, Lexington Avenue and Fifty-second Street, on Thursday, it will be decided whether or not that institution is to be continued. It has been supported for eighteen years upon voluntary contributions, requiring yearly a guarantee fund of $10,000 for its maintenance. This, the governing board, it is said, has had some difficulty in securing for several years past, but it is understood that the guarantee has been raised for this year, and that means have been provided for the institution's yearly expenses in the future.

Academy of Medicine.—A meeting of the Section on Laryngology and Rhinology will be held Wednesday evening, February 27th. The following is the program: (1) Exhibition of Specimens and New Instruments. (2) Presentation of Cases. (3) Paper: "A Remarkable Case of Glosso-Pharyngo-Labial Paralysis," by Wolff Freudenthal, M.D. (4) Paper: "A Combined Intra- and Extra-Nasal Operation for the Correction of a Congenital Concave Vertical and Lateral Deformity of the Nose; with Report of a Case," by B. S. Booth, M.D.

The Section on Obstetrics and Gynecology will meet Thursday evening, February 28th. After the scientific session the election of officers for the year will be held.

PHILADELPHIA.

Neurological Society.—Officers for the ensuing year are: President, Dr. James Tyson; Vice-Presidents, Drs. C. S. Potts and F. X. Dercum; Secretary, Dr. A. A. Eshner; Treasurer, Dr. G. Hinsdale.

Army Commissions for Pennsylvania Physicians.—The following appointments to the regular army have been made: Dr. R. H. Zamer, of Norristown, Surgeon with rank of Major; Dr. J. S. Kennedy, of Chambersburg, and Drs. I. E. Bennett, H. H. Kiersted, and F. S. Dale, of Philadelphia, Assistant Surgeons.

Children's Hospital of Germantown.—The medical staff of this institution will in the future be composed entirely of homeopathists. The Board of Managers placed the names of several homeopaths on the list of visiting physicians. The

regular members thereupon resigned and their places were filled by the appointment of homeopaths.

Brains Bequeathed for Scientific Study.—The recent appeal of Dr. Spitzka of New York recalls the fact that some twelve years ago a small number of eminent Philadelphia medical men made an agreement to bequeath their brains to their survivors for scientific study. Among these were the late Drs. Pepper, Leidy, Allen and Wormley. The brains of at least two of this number are now in the Wistar Museum.

Pennsylvania Hospital for the Insane.—Dr. A. R. Moulton reports a case of rupture of the rectum with hernia of the intestine. The patient was a man of thirty-four years who had several years ago manually produced a rectal prolapse. In November, 1900, the rectum ruptured and two feet of small intestine and mesentery protruded. Shock was profound, death following in thirty-six hours.

A stated meeting of this Society will be held on Monday, February 25, 1901. Dr. Wm. H. Teller and Dr. F. X. Dercum will exhibit "A Case of Astereognosis," and Dr. George L. Walton and Dr. Walter E. Paul of Boston, will, by invitation, read a paper entitled "Astereognosis: with Illustrative Cases." At the close of the meeting a reception will be tendered Dr. Walton and Dr. Paul at the University Club. Members and others are cordially invited.

Dr. Cabot in Philadelphia.—Dr. Richard C. Cabot of Boston visited this city last week and addressed the Stillé and University Medical societies at the University of Pennsylvania on Thursday and Friday evenings. Dr. Cabot's subject at the latter meeting was the percentage of failures in diagnosing valvular lesions of the heart as shown by clinical diagnoses and the results of autopsies. The subject was discussed by Drs. Musser, Tyson, Hare, Stengel, Edsall and others.

International Congress of Nurses.—Miss Maud Baufield, of the Polyclinic Hospital, who has labored very earnestly for the organization of nurses, is to be the Secretary of the Congress which meets at Buffalo during the Exposition. The speakers at the meeting will include, besides the representatives of various American societies, Mrs. Strong of the Royal Infirmary, Glasgow; Mrs. Huxly, of Dublin; Miss Florence Nightingale and Mrs. Bedford Fenwick of London.

Hasty Embalming.—The Coroner's inquest upon the body of a man found dead in the street February 15 developed the fact that a full autopsy by the coroner's physician was impossible because the body had been embalmed before the physician reached the place. This is the third case within two weeks in which the investigation of the coroner has been complicated by too hasty embalming. A bill to prevent the embalming of bodies by undertakers before they have been authorized by the proper parties is now before the legislature.

Treatment of Tuberculous Glands of Neck with Minimal Scarring.—Dr. G. Betton Massey uses a method which instead of the unsightly scars left by cutting operations leaves only points of scar tissue. A small opening is made in the skin over the affected gland and the tissues slightly cauterized with an electrode to keep the opening patulous. At intervals of a few days a gold electrode fully amalgamated with mercury is introduced and a current of two to ten milliamperes is passed for ten minutes. It is claimed that the tubercle bacilli are destroyed by the liberation of nascent oxychloride of mercury. Two cases of cure are reported. The sinus allows drainage of the waste products and afterward closes with but a point of scar tissue.

Diagnosis of Pancreatic Disease.—At the Pathological Society February 14th Dr. D. L. Edsall spoke of the diagnosis of pancreatic disease by the estimation of the urinary sulphates and of the fecal fat. Two cases were cited as illustrations. In one, a man of thirty-six years, there were gastric symptoms and jaundice together with other symptoms suggesting pancreatic disease. An estimation of the urinary sulphate showed the ethereal to be less than half the usual amount, the ratio between ethereal and preformed being 1 to 29 and 1 to 20 on different days instead of 1 to 10, the normal. Autopsy showed carcinoma of the head of the pancreas. Case second, a woman of forty-eight years showed an increase of the ethereal sulphates the ratio being 1 to 7.4 and 1 to 8.5. The woman recovered having apparently had an attack of catarrhal jaundice. Dr. Edsall believes that the study of the ethereal sulphates is of value in cases of suspected pancreatic disease, a positive result being relatively of more value than a negative one. In regard to the fecal fat there is a rather prevalent idea that fat in the stools means pancreatic disease. This is an erroneous belief, as there is fat in normal stools. The importance of icterus in connection with fat in the stools was emphasized. In the second case referred to there was a large amount of fat in the stools. The conclusion reached is that fat in the stools is not of much value in proving the existence of pancreatic disease. Indicanuria is not considered of diagnostic value in any disease.

CHICAGO.

Will of Albert A. Munger.—According to the will of the late Mr. Munger, the following institutions are beneficiaries. Fifty thousand dollars will be divided among them: Woman's and Children's Hospital, the Chicago Foundlings' Home, the Chicago Nursery and Half Orphan Asylum, and the Home for Incurables.

Colony for Epileptics.—The scheme of a State colony for epileptics at Grand de Tour in Ogle County has been put into a bill and introduced in the House by Representative David Hunter. An appropriation of $350,000 to start it is asked. The restrictions thrown around admission to

the proposed Colony are much the same as the restrictions on admission to the Insane Hospital. Board, tuition and treatment are to be given colonists by the State, and also their clothing, if they are poor.

Three Cases of Osseous Stylohyoid Arch.—These cases were reported at a recent meeting of the Chicago Pathological Society by Dr. T. R. Crowder. Complete osseous stylohyoid arch is a comparatively rare anomaly. It is to be considered as a developmental reversion to a lower type and not as an ossification of the stylohyoid ligament once developed in the normal way. In the cases presented the four original skeletal elements of the second branchial arch (hyoid bars or Reichert's cartilages) are represented by separate articulated bones. At the same meeting Dr. F. G. Harris reported a case of blastomycetic dermatitis; while Dr. A. C. Gillam detailed a case of angiosclerotic ulcer of the vagina and cervix uteri.

Fourth of July Tetanus in Chicago.—Dr. H. Gideon Wells read a paper with this title. Following July 4, 1900, there occurred 27 cases of tetanus due to wounds from explosives. The preceding year there were 17 from the same cause. An investigation made to ascertain the source of the infecting organisms demonstrated their absence in the wads of 250 blank cartridges of various makes, but in one of six samples of street dirt from various parts of Chicago they were found. Investigation showed that in nearly every case the physician in charge had neglected to remove the wads and other foreign particles from the tissues, and no consideration whatever had been given to the possibilities of the tetanus infection. Considering the frequency of tetanus in blank-cartridge wounds in this city, and the very positive value of tetanus antitoxin as a prophylactic, the writer urges the injection of five c.c. of antitoxin in all such cases when first seen, in addition to thorough cleansing and drainage, usually under anesthesia.

Education of Deaf and Deaf-Mutes by Means of Aural Exercises.—Dr. E. F. Snydacker read a paper on this subject before the Chicago Medical Society. It has long been known that deaf-mutes retain certain remnants of hearing. Bezold has shown that if these remnants of hearing lie within that part of the scale, the number of vibrations of which corresponds to the number of vibrations of the human voice, *i. e.*, from b^1 to g^3, the hearing of these deafs can be wonderfully stimulated and augmented by aural exercises. These exercises cannot change pathologic processes, but they do stimulate and augment such powers as exist. They combat the apathy into which such patients fall; they bring new brain centers into play by overcoming states of aphasia into the ear until mental acoustic images are given chiefly by means of the human voice; objects are shown children and their names shouted into the ear until mental acoustic images are aroused. If they are old enough, letters are shown and their names shouted into the ear until they can be repeated. The vowels are taken and repeated until they can be correctly understood. The child, almost at once, makes efforts to speak. After the vowels, consonants are taken, and very soon simple words and simple combinations of words. If the child possesses the requisite range of hearing, improvement continues until conversation can be understood. A certain percentage, by no means insignificant, of the inmates of deaf and dumb asylums are adapted for this training. If the requisite range of hearing is not present, or if the children are simple-minded or idiotic, the exercises are wasted labor. These exercises have been officially investigated and adopted in Bavaria, Baden, and other German States, and are also employed in many institutions in Austria.

State Sanatorium.—A bill for the establishment of a sanatorium in Illinois was introduced by Representative Warren a few days ago. This bill was framed by Dr. John A. Robison of this city in accordance with the suggestions of the Legislative Committee of the Illinois State Medical Society, of which he is a member. It also has the endorsement of the Illinois Society for the Prevention of Consumption, the State Board of Health, and the medical profession generally. The bill asks for an appropriation of $200,000 for the purchase of a site, the erection of the building, and the maintenance of the institution for one year. It provides that the sanatorium shall be in charge of three trustees and under the superintendency of a practising physician, who shall be a graduate of some school recognized by the State Board of Health. The resident physicians are to be selected on competitive examination, conducted by the State Board of Health, and the cost of treatment of indigent patients is to be defrayed by the counties in which they reside. Special safeguards are contained in the bill to prevent the encroachment of politics into the management of the institution. Dr. Robison said it is a shame that Illinois has no place for the treatment of persons afflicted with tuberculosis, when it has been conclusively demonstrated that the disease is curable. The bill has been framed with the idea of giving a close supervision to the daily life of patients and according them hygienic treatment which will enable them to resist the disease. Dr. George W. Webster said it is necessary that a sanatorium should be established, not only for the curing of consumptives, but also for the protection of all who are not afflicted with the disease. Dr. J. B. Murphy said the idea is a most excellent one. Such a sanatorium will fill a long-felt need of the State and community in general. If it is run for the purpose of curing tuberculosis and not as an antemortem resting-place, it will be a monument to the wisdom of the State Legislature for all time. The greatest blot on the reputation of Chicago as a progressive city is the fact that if a poor person is afflicted with consumption he must go to the poorhouse for treatment. A

sanatorium for consumptives can produce more beneficial results for the human race than any other form of public institution for the care of the sick.

GENERAL.

Western Ophthalmologic and Oto-Laryngologic Association.—This society will meet in its next annual session in Cincinnati, Ohio, April 11th and 12th. An interesting program has been arranged and the medical profession are cordially invited to attend the sessions. Dr. C. R. Holmes of Cincinnati is Chairman of the Local Committee of Arrangements. Dr. M. A. Goldstein of St. Louis is the President, and Dr. W. L. Ballenger of Chicago is the Secretary.

Obituary.—Dr. William Rice, Mayor of Trenton in 1879 and 1880, died suddenly in that city last week. He was sixty-three years of age and one of the oldest practising physicians in the city.

Dr. J. H. Linsley, Director of the State Laboratory of Hygiene and State Bacteriology, died at Burlington, Vt., last Sunday. He was born in Windsor, Vt., in 1859. He was appointed in 1887 an instructor of clinical microscopy in the New York Post-Graduate Medical School and Hospital. Later he was made director of the Laboratories of Histology, Pathology and Bacteriology, also pathologist to the New York Post-Graduate Hospital and the New York Infant Asylum. In addition he did some pathological work for the St. Luke's and the Presbyterian hospitals. He went to Germany as representative of the New York Post-Graduate Medical School. He gave the first address on lymph treatment for tuberculosis in this city.

CORRESPONDENCE

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, Feb. 9, 1901.

THE REPORT OF THE SOUTH AFRICAN HOSPITALS COMMISSION—THE CHARGES OF MR. BURDETT-COUTTS NOT SUSTAINED—EXONERATION OF THE ARMY SURGEONS—BLAME FIXED ON THE RIGHT SHOULDERS OF THE WAR OFFICE NEED OF REFORM—AN EFFETE SYSTEM—INADEQUACY OF THE ARMY MEDICAL STAFF—IGNORING BY THE WAR OFFICE THE DEMAND FOR MORE AMBULANCES—APPLIANCES OUT OF DATE—TOO MUCH MILITARISM IN THE HOSPITALS—COMPLAINTS AGAINST ORDERLIES—THE APPOINTMENT OF SPECIAL SANITARY OFFICERS RECOMMENDED—THE CONDITIONS OF AFFAIRS AT BLOEMFONTEIN—TYPHOID PATIENTS ATTENDING ON THEMSELVES—OUTBREAK OF SMALLPOX AT GLASGOW.

The Blue-book containing the report of the Royal Commission appointed to inquire into the medical service in the South African War has been issued. The Commission first met on July 23th. They held seven sittings in England and then went to South Africa where they took evidence and inspected the hospitals, traveling over the whole of the lines of communication from Cape Town to Bloemfontein and thence to Pretoria. They returned to England at the end of October. The main results of the inquiry are the conclusions that the medical and hospital arrangements have not broken down; that there has been nothing of the nature of a scandal with regard to the care of the sick and wounded and no general and widespread neglect of patients or indifference to their sufferings. All the witnesses of experience in other wars were unanimous that, taking it all in all, in no campaign have the sick and wounded been so well looked after as in this. But the Royal Army Medical Corps was deficient, defective in organization and training and imperfectly equipped with appliances. As I have repeatedly said in my previous letters, the army surgeons were in no way to blame. It is the old story over again, deplorable want of foresight and common sense on the part of the War Office and Herculean efforts on the part of its servants. The muddling of the War Office has not been confined to purely military matters. As I have before pointed out the Medical Corps is not master in its own house; it has no transport service of its own and its demand for supplies can be refused or granted by non-medical officers.

The fact is the Medical Corps has always been snubbed and treated with as much contempt as possible by the military authorities, simply because it is composed of men who practise their profession as a means of living and are not members of an aristocracy, or more often plutocracy, who enter the army because it is fashionable and a good club. As a natural result the knowledge of warfare as a science possessed by these men is of the slightest. Hence the lamentable blunders of this campaign. This is not perceived at all, or only dimly so, by the average Englishman who has to pay for their blunders so dearly, both in taxes and in the blood of his kin. He absolutely fails to grasp the elementary fact that war is a matter of science and not of snobbery. Is it any wonder that men who bungle in military matters, about which they are supposed to know something, should bungle in the control of medical matters of which they know nothing? As a result of this inquiry we shall, of course, get reforms. In fact everybody is crying for the reform of the War Office, the deficiencies of which are at last dawning on the complacent conservatism of the average Englishman. But I am quite certain they will not be nearly as radical as they should be. We have a reactionary Tory Government in office which from its very nature is in sympathy with obsolete and effete prejudices. However high may be the value of the scientific work done in Great Britain and however devoted the workers, the position of science in the eyes of the mass of the people and for the upper classes is a poor one. Snobbery and the gross materialism of wealth are the only ideals of these people. When this is understood you have the ultimate cause of the difficulties in South Africa, military and medical.

As to the general inadequacy of the medical

staff of the Army the Commissioners say that the military and medical authorities never anticipated that this war would have been of the magnitude which it has attained. The Medical Corps was totally insufficient and it was not so constituted as to be capable of enlargement nor to have its deficiencies made good. This was not the fault of the Medical Director-General and his staff. For a considerable time before the outbreak they urged upon the military authorities the necessity for an increase of the Corps, but without avail. The regulation ambulances are condemned by the Commissioners. They say: "We found them very heavy, requiring a large number of mules to draw them, and very jolty and uncomfortable. The type used appears not to have been materially changed or improved for many years." More conservatism! A defect in the equipment of the fixed general hospitals was the lack of transport. Transport was ordinarily supplied by requisition from the Army Service Corps, which led to delay. A fact observed by the Commission was the existence on the part of many military officers of a feeling of distrust of the skill and experience of the Medical Corps as compared with civil doctors. To a great extent the Commission believe this mistrust to be ill-founded. That it is not wholly unfounded is due to the difficulties under which the Corps has labored. In time of peace the Corps has been undermanned and the officers have not had sufficient holidays nor leave nor opportunities of studying and keeping abreast with recent advances in the practice of medicine and surgery.

The Commissioners recommend (1) that the staff of the Medical Corps be permanently enlarged and due provision made for its further necessary and speedy enlargement in times of great wars; (2) that inducements be offered to ensure a continuous supply of men of good professional attainment; (3) that the men who have joined be kept as a body thoroughly acquainted with the general progress in professional subjects and at a high professional standard of efficiency. The means by which these results may be best attained require careful expert investigation and consideration and the Commissioners recommend that they be considered by a departmental committee. In the hospitals the Commissioners found too much militarism—a tendency of some of the officers and still more of the non-commissioned officers and men of the Medical Corps to treat the hospitals too much as barracks and to regard those admitted as soldiers and not as patients. The nurses employed in this war have shown great devotion and the soldiers have much appreciated their services which they prefer to those of orderlies. At the outbreak of war there was available only staff and equipment for two army corps (80,000 men), and even these were equipped with difficulty. The deficiency was made up partly by private hospitals and the wholesale use of civil surgeons and untrained orderlies. But it was never wholly made up. The Army Corps unit allowance of field-hospitals was reduced from 9 to 6. Thus the field hospitals in South Africa were 10 short of the proper number and this defect was never made good and caused a strain throughout the whole campaign. At the time of greatest pressure, the end of March, the total force engaged was about 207,000 men. There were then 800 medical officers, including civil surgeons, 6,000 hospital subordinates and 800 nurses. But it does not follow that this medical aid was distributed in proportion to the needs of particular localities. The movement of troops was often sudden and unexpected. Transport was generally difficult and had in many cases to be used exclusively for the fighting line. Taking their work as a whole, the Commissioners consider that the Principal Medical Officer and his staff did excellent work. They never spared themselves and showed the greatest devotion to duty. Complaints against orderlies was frequent, but this was due to the large proportion of untrained men which had to be employed. On two evils of hospital life it is suggested that the medical officers should be vigilant—the stealing of stimulants and comforts intended for the sick and even their money and other property and the practice of taking bribes. Many complaints were made on this head. The need of special sanitary officers is emphasized by the report. It is suggested that they should be members of the Medical Corps specially qualified and selected for sanitary duties.

Referring to the state of affairs at Bloemfontein in May, which, it may be remembered, was the principal point of Mr. Burdett-Coutt's attack, the Commission says that when the army began to advance toward Kroonstadt the field-hospitals had to be cleared in order to accompany the troops and the patients had to be discharged into general hospitals. As the advance continued the sick and wounded were sent back to Bloemfontein with the result that there was great overcrowding of the hospitals. One hospital, the regular complement of which was 520 patients, had to receive 1,400. The doctors and orderlies were overworked and there were too few nurses. There was a deficiency of necessaries and, the report adds, a want of energy in improvising substitutes or in remedying defects. Patients were not properly nursed and typhoid patients, though probably not of a severe type, had to wash and tend themselves, night stools were not properly emptied, etc. Generally speaking, the difficulties at Bloemfontein were due to defective transport and a violent epidemic of typhoid fever which could not have been foreseen. The Commissioners think the difficulties were not realized as soon as they might have been and that more doctors might have been obtained and sent up earlier.

Small-Pox in New York.—Another nest of small-pox was discovered last week in the upper West Side of the city. Thirteen patients were removed from one building. One patient had died and the others had been sick a week.

NEPHRECTOMY—BACILLUS AEROGENES CAPSULATUS - RADIOGRAPHY AND DIAGNOSIS—CIRRHOSIS MALIGNA —PRIMARY HEPATIC CANCER AND CIRRHOSIS—MITRAL DISEASE—RHEUMATISM AND THE SKIN.

F. Heuston, at the Section on Surgery of the Royal Academy of Medicine in Ireland, November 9, 1900, exhibited a case of nephrectomy for sarcoma of the kidney. The woman, who was twenty-four years old, noted in the winter of 1898 a large painless tumor in the right side, had severe hematuria for three days in February, 1899, but no recurrence of it since, complained of a gradual increment in the mass until September of that year, when it began to cause dragging and pain in the erect position of the trunk. Examination at this time revealed a tumor filling the umbilical and right lumbar regions laterally outward from the linea alba and from beneath the costal arch above to the iliac crest and fossa below, freely movable within the abdomen and beneath the skin, of stony hardness, smooth surface and well-defined border, without tenderness or pain on pressure. February 1, 1900, the usual oblique incision was made for a lumbar nephrectomy and a tumor of the kidney chiefly cystic in character was exposed. The larger cavities were aspirated of a clear limpid fluid containing albumin, but no urea. The pelvis of the kidney was much enlarged and filled by a hard growth which extended down the ureter to the iliac vessels and brim of the true bony pelvis. Beyond this point the ureter appeared normal. Hence it was tied off here, dissected upward to the renal vessels from which its pelvis was separated fully before the blood-channels were ligatured. The extraction of the balance of the tumor was now easy. Uneventful recovery resulted. The total excretion of urine during twenty-four hours increased from twenty-one to forty ounces.

A meeting of the Section on Pathology of this same Society was held November 30, 1900, when E. J. McWeeney gave an account of his recent experiments with the *bacillus aerogenes capsulatus*. A man had had his arm ground almost to a pulp in a thrashing machine and did not long survive amputation, at which a peculiar, gelatinous condition of the tissues was noted. About twenty-four hours after death the corpse presented a most remarkable appearance. It was swollen to at least twice its size and was covered everywhere with large black bullæ and was crepitant wherever touched. The skin was so softened that the point of blunt forceps could be forced through it at any point with perfect ease and out of the holes came frothy fluid made up of turbid serum and sour-smelling gas. Microscopically the fluid was very abundant in a very large bacillus much resembling the anthrax bacillus, capsulated, without demonstrable spores, staining well by Gram's method, multiplying rapidly in anaerobic plate-cultures over alkaline pyrogallol, by which means it was isolated, although not without difficulty. The special dish used for this purpose was then exhibited. Associated with it were the bacillus coli communis and a streptococcus. All three forms grew well in an atmosphere of hydrogen, but not of coal-gas. The best culture medium for the gas-producing germ appeared to be a sodium-sulphindigotate agar.

H. Walsham and E. C. Beale, at the Medical Society of London, January 14, 1900, read their observations upon the value of the skiagraph in the diagnosis of diseases of the chest. Several important conditions must be observed, before a successful issue can be expected. The coil must be one of very high potential, giving a ten- to fourteen-inch spark. A feebler apparatus will fail to be satisfactory. It is necessary to have such a spark some distance from the chest and for photography have the person lie face down upon the couch with the plate suitably protected from damage by light and pressure beneath him. Dermatitis is not a necessary sequel to the use of the skiagraph and seems to be due almost entirely to too frequent exposure at short intervals or to too prolonged exposure at a single sitting, for example, one-half to one hour. Views from various directions are always essential to a good picture and an accurate diagnosis and the best series is from the extremities of a given diameter, for example, from the front and the back, and two oblique views. The vertebræ, rib, scapulæ, clavicles and sternum of the bony frame, the axillary folds of the muscular frame and the individual visceral outline must be well in the mind's eye. The heart has a deeper shadow at the ventricular than at the auricular regions. The lungs are translucent, but their outline is distinguishable by the light line of the pleuræ. Emphysema increases the translucency of the lungs. Thick pleura gives a slight shadow. Clear fluid except at its upper border does not alter the picture much. Pus is always of very deep shadow indeed. Consolidation is like a solid organ. Aneurisms and tumors so alter the relations of the organs and give themselves such good outlines that they are well within the scope of the instrument and lend themselves to very early and exact diagnosis with it. Tuberculous nodules, being really consolidations, are easily recognizable, usually long before they begin to give physical signs.

H. L. Jones said in the discussion that he regards the radiograph as a more valuable means of examination than the ordinary methods of palpation, percussion and auscultation. In aneurism he has seen it indicate the disease when both symptoms and signs were as yet wanting.

H. D. Rolleston, at the Pathological Society of London, January 15, 1901, reported a case of primary hepatic carcinoma secondary to a cirrhosis, the so-called cirrhosis maligna or cirrhosis carcinomatosus. The man was forty-four years old and during life had had hematemesis, hepatic pain and ascites which had required tapping four times. At the necropsy the liver was found cirrhosed and the seat of a primary carci-

noma. There was no other discoverable primary node of cancer anywhere to be found. The growth invaded the liver widely and at the portal vein extended in a wedge-shape formation between the bifurcation of the vein. Microscopically the growth was carcinoma and had spread along the portal vein so that secondary deposits were to be found in other parts of the organ. The cell-arrangement was tubular, not unlike the new bile-duct formation often seen in cirrhosis, and might be called *epithelioma trabeculare* after Hanot and Gilbert. These writers regarded the carcinomatosis and cirrhosis as synchronous, but Sabourin, with whom Rolleston agreed, looked upon the cirrhosis as the precedent lesion. Perhaps the cancer was to be looked upon as an implantation by the cancer neoplasm as yet unidentified.

W. Hunter presented two specimens of primary hepatic cancer grafted upon cirrhosis of the liver, with metastasis in the lungs of each case. The first patient was a sixty-year-old man who was admitted to the hospital for cirrhosis and ascites after a six-weeks' illness. The other man was fifty-five years old and was admitted for cirrhosis jaundice and ascites. Both were systematically tapped, but succumbed. At the necropsy a remarkable similarity of lesion was present, as each had (1) a coarsely-lobulated, hypertrophic cirrhosis; (2) areas of apparently healthy liver-tissue cells scattered through the cirrhosis; (3) cancerous nodules situate in these islands of healthy gland, here and there; (4) metastases in the lungs; (5) no cancer primary to that in the liver; (6) thrombosis of the portal vein. Microscopically the hepatic and pulmonary neoplastic nodes were alike in character. The liver cancer had probably originated in its own normal cells, because many of these were polynuclear and evidently very active in multiplication and metabolism.

J. O'Carroll, at the Royal Academy of Medicine in Ireland, Section of Medicine, on December 14, 1900, presented a man, sixty-five years old, admitted to the hospital May 25, 1900, suffering from marked dyspnea and sleeplessness due to it, also epigastric pain, thirst and frequent micturition. He had a soft systolic murmur at the apex, albumin and sugar in his urine. He was put to bed and signs of fluid found in his right chest, then in his left. Regular tapping was done eighteen times and a total of sixty-seven pints withdrawn. The last tapping was October 30, 1900. Since then most of his symptoms have ameliorated or disappeared. The best diagnosis appears to be mitral insufficiency with acute dilatation.

H. Thursfield, at the Clinical Society of London, January 11, 1901, read notes of a case of rheumatic periostitis and subcutaneous nodules. He was admitted to the wards of the hospital November, 1900, and presented periostitis of the right tibia and diffuse multiple subcutaneous nodules all over the body. There were no evidences of acquired or congenital syphilis, but many of rheumatic infection, stiffness and tenderness over the hamstring muscles and a small effusion into the knee-joint. The heart was slightly dilated, but without signs of endocarditis. Rheumatic periostitis of the ulna was reported in 1889 by A. Garrod and J. Coutts as a rare affection. The occurrence of subcutaneous nodules with no cardiac lesions is a clinical curiosity. W. B. Cheadle has stated that such subcutaneous nodes are a certain sign of very intense infection and almost always point to cardiac disease. W. B. Hadden in 1889 brought before the Clinical Society another case like the author's, namely, with sound heart although he had the cutaneous deposits.

SOCIETY PROCEEDINGS

THIRD PAN-AMERICAN MEDICAL CONGRESS.

Held at Havana, Cuba, February 4-7, 1901.

(Continued from page 284.)

SECTION ON LARYNGOLOGY, RHINOLOGY AND OTOLOGY.

Tuesday, February 5th.

Otitis and Mastoiditis in Eruptive Diseases.—Dr. A. B. Duel of New York read this paper based on a series of 5,000 cases of measles, scarlet fever and diphtheria, in many of which acute otitis media and mastoiditis occurred as complications. In cases with dual affections the complications were especially prevalent and difficult to treat. Infection takes place mainly through the Eustachian tube and operative procedures alone are capable of giving the best results. Bacteriological examinations of the throat and of the exudates were valuable aids to diagnosis.

In the discussion Dr. Martinez of Havana said that he has always been surprised not to find more cases of mastoiditis in Cuba in proportion to other ear troubles, and finds in Dr. Duel's paper a possible reason for it. Eruptive fevers in Cuba generally run a very mild course, and scarlet fever especially is of such a mild type that often the cases are not cared for; aural complication from this source is therefore rare. The same can be said of measles and diphtheria (in the latter disease on account of the rapid action of the serum). Most of the cases occur as a complication of grip. In reference to operative treatment, he is in favor of the total resection of the mastoid. After having seen it practised by Dr. Whiting of New York, he has operated on a patient in this manner, obtaining a rapid healing; the whole mastoid process was full of soft granulation tissue.

Dr. E. Andrade of Venezuela said that he considers grip the most important factor in the causation of suppurative otitis media and its complications. Being in Genoa last winter during an epidemic of grip, he found that most of the cases were produced by this disease. He is in favor of a radical operative treatment which destroys the posterior wall of the meatus, establishing a free

communication between the antrum and the tympanic cavity. In New York he recently saw a case operated by Dr. Arnold Knapp by Ballance's method, covering the cavity with a skin-flap. The case was doing well at the time.

Dr. G. Landa of Cienfuegos believes that grip is a more common cause of otitis media than the eruptive fevers. He insists specially on irrigating the cavum and entrance of the Eustachian tube with some antiseptic solution as a prophylactic measure, considering this the constant way of infection of the tympanic cavity.

Dr. Duel in closing said that he has not pretended to establish the causes of suppurative otitis media, but to present the relative frequency of this disease as the complication of eruptive fevers; cases of these fevers are the only ones admitted to the institution in his charge. He also points out the severity of cases produced by double infection (measles and scarlet fever) and the necessity of practising a bacteriological investigation in all cases; it is an important measure to operate early in all cases to obtain the best results.

Pharyngeal Hemorrhage and Hemoptysis.—Dr. G. Landa of Cienfuegos read a paper on this subject. He said that in some cases hemorrhage from the pharyngeal wall was so excessive as to give rise to the opinion that pulmonary hemoptysis had taken place.

Dr. Martinez observed that this complication was not unusual in chronic paludal poisoning, especially following operations, and that the administration of quinine was sufficient to prevent its recurrence.

Chloroform Apparatus.—Dr. R. Garcia Rijo of Sancti Spiritus then presented an apparatus to be used in operations about the nose. It is made of tin sheeting and has some rubber tubing leading to the nose.

Laryngeal Inhibition of Respiration.—Dr. E. Martinez of Havana said that Rosenthal, while studying the physiology of the branches of the superior laryngeal nerve, found that when the internal branch or the root of the superior larynx was excited electrically the respiratory functions of the diaphragm were immediately suspended, but that it did not occur on exciting its external branch destined to the crico-arytenoid muscle. This experimental fact has received its clinical confirmation in an operative accident on extirpating papillomata from the larynx. Reference was made to a girl in whom the respiration was twice suspended while the author was curetting a papilloma.

Wednesday, February 6th.

Prevention of Stammering.—Dr. H. Makuen of Philadelphia read a paper in which he laid particular stress on the efficacy of correct breathing, as an aid to the prevention of this difficulty. Constant respiratory exercise is the keynote to the cure. The patient should not think of what he is saying so much as how he is breathing. Diaphragmatic breathing is to be carefully controlled and gotten under the will of the patient. The causes of stammering are multifold, but the main cause is probably largely psychical.

In the discussion Dr. Desvernine of Havana referred to a case of stammering in a woman cured by the operation of a lingual adenoid. He differs from Dr. Makuen in considering the cause as an organic lesion of the central nervous system.

Dr. Andrade compared stammering to strabismus, that is, as a disorder of binocular vision by an incoordination of muscular action in the same way the laryngeal muscles maintain an incoordinate action in stammering.

Dr. J. Mullen of Houston agrees with Dr. Makuen as to the cause of stammering and specially in the manner of preventing it. He referred to a case of a boy, three years of age, who was not only a stammerer, but also was unable to swallow solid food and was fed exclusively on milk. Following Dr. Makuen's directions he was submitted to physical training during three months. Internal pressure on the tongue and external pressure on the neck taught him to swallow solid food and later he was able to articulate several phrases distinctly without stammering.

Dr. Makuen said in closing the discussion that after five years of experience, during which time he has treated over five thousand cases of stammering, he really does not know the cause; it is like the cause of asthma, unknown to us. Speech is an acquired faculty and he wonders why all people do not stammer. It is not an organic disease, but he mentions the fact that 33 per cent. of the cases show a history of inheritance. Possibly they inherit the nervous disposition. To say adenoids produce stammering is misleading. It may induce the habit in a nervous case predisposed to it; in the case referred to in the paper just read the child had physical training before and after the operation. In the same way any nasal obstruction, such as a deflected septum, may be the cause of this disease. The operation will only place the patient in a suitable condition for physical training. He referred to a case of a woman who stammered for thirty-six years and broke the habit by physical training with such a success that she afterward opened a studio in New York to cure stammerers. This patient was persuaded that she could break her habit and she set to work so earnestly that at the time of the third consultation she was cured.

Suppurative Mastoiditis.—Dr. Finlay read a paper giving the clinical histories of two cases of this affection in which cerebral symptoms developed. Dr. Landa said that the dehiscence of the petrosal suture was in many instances the avenue by which infection of the cranial cavity took place.

Dr. Andrada thought that the cerebral symptoms noted by Dr. Finlay were quite notable. He cited a case of Dr. Strasse of Genoa in which abscess of the temporal lobe developed without showing any signs of papillitis. Hence this diagnostic symptom is not always present. Radical operation was necessary since no internal remedies were of value in cerebral involvement.

Dr. M. Herrera of Mariano insisted on early operative procedures.

Dr. Desvernine adopted a more conservative attitude. Many cases are certainly benefited by early operation, but some cases recover without such operation.

Dr. Finlay, in closing the discussion, maintained that operative procedure was alone of value and should be used in all cases. He did not trust to the ordinary routine non-operative methods.

Pharyngo-Laryngeal Paralysis.—Dr. C. M. Desvernine of Havana read an interesting study of a case of Avelli's type of pharyngo-laryngeal hemiplegia, in which he discussed at length the anatomical, physiological and pathological features of the facial, pneumogastric and Will's accessory nerves, especially in relation to their distribution in the soft palate and in the larynx. He further presented a study of a human monster in which he had made research bearing on these same points. The paper is exhaustive and technical, but is a noteworthy addition to our knowledge of the peripheral distribution of some of the more important cranial nerves.

Dr. Andrada then reported the case of a man with the symptoms of acquired syphilis, who was treated in Prof. Secondi's clinic for a paralysis of the internal rectus of the left eye and of a sharp, intermittent and painful contracture of the abductor muscles of the right eye. Antisyphilitic treatment by injections of bichloride and potassium iodide was unavailing. He then made a tenotomy of the muscles of the external rectus of the paralyzed eye and a similar operation on the right eye. Although absolute results could not be hoped for, the paralyzed eye recovered its function and the contractures of the muscles of the right eye disappeared. These results are significant as bearing on our knowledge of the innervation of the ocular muscles.

Dr. Landa thought that the study of Dr. Desvernine was an important step forward in our knowledge of the important signs by which one could differentiate between central and peripheral paralyses of the facial nerve, paralysis of the velum furnishing the important diagnostic symptom.

Dr. Andrada spoke of having seen a similar case in Dr. Knapp's clinic in which there was no paralysis of the velum.

Foreign Bodies in Air-Passages.—Dr. A. W. de Roaldes of New Orleans read this paper. In presenting sixteen cases of foreign bodies in the lower air-passages, the author points out the fact that the twelve recoveries that took place had been operated upon, while the four deaths were among the cases that refused the operation. Dr. de Roaldes adds that leaving aside all consideration of statistics, which are at times misleading, he wishes to put himself on record as the result of his personal experience, for advocating in most cases an early surgical intervention. Apart from the question of foreign bodies in the larynx, the treatment of which is pretty well agreed upon, he says in conclusion: (1) That the presence of a foreign body in the trachea is always a more or less serious accident; (2) that in such cases prompt and proper action must be resorted to, in order to anticipate swelling and ulceration of the mucous membrane and any infectious process resulting from the prolonged presence of the foreign body; (3) that this indication is best fulfilled by a tracheotomy, at a level most suited to the requirements of the case; (4) that if not coughed up shortly after the opening of the trachea, the foreign body should be located by means of tracheoscopy and of bronchoscopy, and its extraction effected, is possible, under a light, and with improved instruments. In closing, he adds that in the question of foreign bodies in the air-passages, as well as of those in other regions, radiography may be very useful for such substances as are susceptible of being located by this process. As to metallic bodies that are magnetic, he suggests the trial of Haab's giant magnet, which under certain circumstances might prove of great value by placing it before the mouth or before the tracheal wound, according to the situation of the foreign body.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE—SECTION ON MEDICINE.

Stated Meeting, Held January 15, 1901.

J. H. Huddleston, M.D., Chairman.

Mosquito-Malaria Theory.—Dr. W. N. Berkeley said that in the neighborhood of New York two forms of the *Anopheles* mosquito, the malaria-carrier, are quite common. These are the *Anopheles quadrimaculatus*, so-called because of the four spots on its wings, and *Anopheles punctipennis*. The former is common, the latter rarer. The *Anopheles* mosquito can be distinguished from other common varieties because its palpi are as long as its proboscis and the commonest variety has spots on its wings. The posture of the insect of the genus *Anopheles* has often been said to be characteristic. Dr. Berkeley has made a special study of this subject and is of this opinion. Posture alone, however, is not an exclusive method of recognizing the insects. Dr. Berkeley has often caught specimens of *Culex* that were not resting parallel to the wall or ceiling on which they stood, but somewhat at an angle. This posture at an angle is usual with *Anopheles*. The *punctipennis* variety is found very commonly in The Bronx region, especially in the neighborhood of Jerome Park. *Quadrimaculatus* is found in all of the suburbs of New York where malaria occurs. So far as known no malarial district is without some variety of *Anopheles*. Considerable study has been devoted to this question as regards the vicinity of new York, so that this of itself is an interesting confirmation of observation made in other countries.

Interesting Facts.—There are certain places especially on Long Island where, notwithstanding the fact that *Anopheles* mosquitoes are reasonably frequent, there is no malaria. In one or two of these places the nights are so cool during the sum-

mer that the inhabitants sleep under blankets. It is probable that this coolness of the nights has much to do with the failure of malaria to develop. A few cases of malaria have been noted in and around New York, near which no specimens of *Anopheles* could be found. The mosquitoes were looked for, however, only in the day, while it is usually at night that they are on the wing. The malarial mosquitoes are found most often in foul, ill-ventilated and dark rooms. These, of course, are mainly the apartments of the poor. Needless to say it is in this class that malaria is most frequent. The *Anopheles* practically never bites during the day. In this it differs from the more common mosquito *Culex*, which is particularly ravenous during the day.

Earliest Malaria.—The earliest cases of malaria in the spring depend upon the date at which *Anopheles* bite. This is not definitely decided as yet. The earliest fresh cases of malaria reported in Italy occurred about the middle of June. Dr. Berkeley thinks that he found, in the case of a gardener at Larchmont, one in which a fresh malaria developed on March 16th. Therefore the patient must have been stung by a mosquito about March 1st. As a rule, cases of malaria which occur in the spring are relapses from previous attacks of the disease. The patient in Dr. Berkeley's case was an intelligent Scotchman, who had not had malaria for ten years, and the most probable explanation of the origin of the disease seemed to be that it was primarily acquired some two weeks before its onset. *Anopheles* does not hold over during the winter, except in the case of impregnated females which may be discovered hibernating. This is a well-known fact. In the neighborhood of New York *Anopheles* has frequently been discovered about Christmas clinging to the wall in dark places. It is interesting to note how few the male mosquitoes are in number. It is always the females who sting.

Forms of Malaria.—Tertian malaria occurs quite commonly. Fresh cases of it can be studied among the workmen at the Jerome Park reservoir. Quartan fever is much more rare and a case in which a positive diagnosis could be made has not yet been observed. Cases in which crescents occur, that is, crescentric forms of the malarial parasite, are not influenced by the administration of quinine.

Inoculation of Malaria.—The artificial production of malaria in the human being was tried in the case of a resident at the Presbyterian Hospital who volunteered for the purpose. He was stung by a malaria-bearing mosquito and fourteen days later developed some temperature and diarrhea and even had a chill. The symptoms did not continue, however, passing off after twenty-four hours and no parasites were found in his blood.

Malaria in Manhattan.—Only one case of malaria that seemed to have been acquired on Manhattan Island has come under Dr. Berkeley's observation. This was a young boy, living on Tenth Street, who had not been out of Manhattan for some time. All the other cases of malaria investigated were evidently imported from outside Manhattan. So far *Anopheles* mosquitoes have not been discovered on Manhattan Island. This subject is an interesting one for investigation and one in which many observers could share with interest and at the same time with value to medical science. The exact period of incubation, that is, the length of time between the bite of a mosquito and the development of symptoms of the disease, was observed in one case. The patient had not been out of the city for several years. She went only once to Fordham to nurse a sister and three children who were suffering from chills and fever. Exactly fourteen days after her return she had a chill; she did nothing for it and two days later had another, and two days after this she had a third chill. Then she consulted a physician. Her blood was found to be swarming with malarial parasites.

Prophylaxis of Malaria.—In non-tropical countries there seems to be some hope of completely exterminating the disease. The important measures are the rigorous quarantine of malarial cases in human beings. They must be so guarded that it is impossible for mosquitoes to get at them. The second important precaution is the prophylactic use of quinine. Dr. Berkeley has had one opportunity to test the effectiveness of prophylactic measures in the neighborhood of New York. The first case of malaria occurred in a coachman and then other servants in the house were attacked and cases occurred in surrounding houses. An abundance of *Anopheles* mosquitoes of the *quadrimaculatus* type were found to exist in the neighborhood. For the extermination of the mosquito certain pools which existed in the neighborhood were drained off and filled in. Screen-doors and window-screens were put in position. In addition to this infected cases were carefully surrounded by mosquito-netting, especially at night. The results of these precautions were promptly seen and no more cases occurred. For the extermination of malaria in the vicinity of New York certain measures are advisable. The City Health Board should require all cases of malaria to be reported exactly as is done in scarlet fever or measles. A code of instructions should be issued to enable people to recognize and kill *Anopheles* mosquitoes. Stagnant pools of water should either be drained and filled in or should be heavily petrolized. In an infected neighborhood quinine should be freely used, and it should be supplied at public expense to people who have not the means to pay for it. Those affected by the disease should be carefully guarded from the possibility of being bitten by mosquitoes and thus spreading the disease. In an island near the Italian coast these measures, rigorously enforced, have proved successful in exterminating the disease, although it existed for a long time in virulent form.

Malarial Dangers in Our Cities.—One great source of danger in New York and in American cities generally is the present mode of extending streets out into uninhabited districts. Streets are raised to grade and owners are permitted to delay the filling in until such time as they are ready to improve their property. This gives occasion for

large stagnant pools of water that exist all the year around. These pools form favorable breeding-ground for the *Anopheles* mosquito. The existence of these pools makes local eradication of the disease practically impossible.

Greatest Discovery of the Age.—Dr. William H. Thomson said that the more one reflects on the mosquito-theory of the distribution of malaria the more one becomes persuaded that its discovery is an important event in the history of medicine—more important even than the discovery of the germ that causes tuberculosis. The finding of the true source of malaria brushes away at once all the old ideas with regard to essentially-unhealthy climates. An unhealthy climate is always an infected climate. It is not soil and air and water, nor changes in them, that cause disease, but the fostering of germ-life. If a sanitarian were given the price that it costs to build one ironclad he could disinfect the most unhealthy place on earth. These important facts with regard to malaria should be brought before the notice of the general public. We owe it to them to make them acquainted with the latest developments of medical science that can accrue to their benefit. It has always been the custom of the profession to instruct them. It is now a duty.

Italian Malaria.—Dr. James J. Walsh said that as the result of Italian investigation with regard to malaria the feeling in Rome as to the disease has changed very much in recent years. There is now the greatest confidence exhibited that before long the city shall be entirely free of the disease. American students in Rome feel that if they protect themselves at night from mosquitoes they are sure to avoid the dreaded Roman fever. At Albanella, near Naples, where malaria of the most virulent form has existed since early Roman times, a small colony of Italian scientists demonstrated that it was possible for people who had never had malaria to dwell in the most malarial part of the region a whole summer without contracting the disease.

Estivo-Autumnal Malaria. — Dr. Morris Manges said that this type of malaria is often said to be rare in New York, but it is much more frequent than it is thought to be. Careful blood-examinations, especially since the Spanish war, have made physicians more generally familiar with the parasite of this type, and have shown this to be true. Another erroneous notion that is being eradicated is that children rarely suffer from malaria. Koch has found that in South Africa the children are quite frequently attacked, and this has been Ross's experience in India. Malaria used to be considered a curiosity in children, but it is much more frequent than has been thought.

Present-Day Grip.—Dr. William H. Thomson said that diseases alter but little in the course of years. The course of the same disease in two different seasons may present notable differences, but the manifestations of the disease in a series of years present a picture that approaches very closely a definite disease type. An exception must be made in this regard for influenza, the clinical symptoms which have certainly grown milder since the first invasion of the disease and the great epidemics of 1899, 1890, and 1891. Serious cases still occur, but they are rare. Dr. Thomson has recently had under his care four cases of delusional insanity due to grip. They were transient in character, but very acute while they lasted. In some recent cases chronic meningitis has followed as a sequela of influenza. Another case was followed by extensive desquamation of the skin. In older patients acute gastritis is sometimes a serious manifestation of grip and may prove almost fatal. In one case seen recently the principal symptom was a sweat so profuse that fluid dripped from the bed. In a physician, who was suffering from grip, acute nephritis developed and was followed by chronic Bright's disease.

Symptomatic Treatment.—This is all that can be accomplished for the disease as there is no specific remedy known. The most prominent symptoms at the beginning of the disease are the aches and pains in the bones. For the relief of the general aching which occurs at the beginning of infectious diseases aconite is the best drug. This modifies capillary congestive states, quiets the heart and brings the circulation back as nearly as possible to a normal condition. After aconite the drug that gives most relief is Dover's powder. With these should be combined some one of the coal-tar analgesics and phenacetin has proved the most useful. This should be given as an analgesic and not as an antipyretic. Dr. Thomson's favorite prescription is the following:

℞ Aconite, solid extract.... gr. j-vj
Dover's powder..... gr. j
Phenacetin ..... gr. viij
Quinine ..... gr. vj

This is sufficient for two pills. Of these pills six should be taken the first day and each succeeding day until the fever subsides. Then three should be taken every day, until all the catarrhal symptoms have disappeared. These pills are made up by many of the manufacturing pharmacists.

If there is considerable dryness, discomfort and irritation of the throat, a quart of hot water should be used to irrigate it. In the water should be dissolved two drams of potassium chlorate and five drops of oil of peppermint. In order to secure the distribution of the oil of peppermint through the water, it should be dropped upon the chlorate of potash before this salt is dissolved in the water.

Supra-Orbital Neuralgia.—It is a characteristic of grip to produce painful affections of the accessory sinuses and the supra-orbital pain which results from this is often almost unbearable. A certain amount of photophobia is often associated with the pain and patients are in great misery. These pains often recur at regular intervals and a favorite time for their recurrence is the morning hour. Patients are often entirely comfortable at night. The best remedy for these

is a dram of ergot given every three hours in combination with a dram of cinchona. Ergot is the ideal remedy for periodical neuralgias. When quinine and Warburg's tincture have failed to give relief it often proves of immediate service.

Paroxysmal Cough.—Patients suffering from grip are often troubled by a paroxysmal cough, which is most disturbing at night. For this ammonium bromide in twenty-grain doses, in combination with ten grains of antipyrin, will often give relief. These paroxysmal coughs seem to be dependent at times on a viscidity of the mucus secreted during the influenza bronchitis. The presence of this thick mucus sometimes blocks small bronchi and so leads to the development of areas of capillary bronchitis. The disturbance of the ventilation of certain areas of the lungs leads to loss of tone and to the occurrence of patches of peripheral lobular pneumonia.

Emulsion of Linseed Oil.—An important indication in cases of grip is to liquefy the mucous secretion of the disease. The ammonium compounds often failed to do this, especially in the smaller bronchioles. The best expectorant for the purpose is the emulsion of linseed oil, which has no equal. It has been sold in recent years as a proprietary remedy. It may be combined with one eighth-grain of opium and eight grains of chloral and administered every four hours. Counterirritation must not be neglected in these cases. Large cloths should be wrung out in warm water to every pint of which one dram of capsicum has been added. If fine râles exist at the base of the lungs, as will be found to be the case oftener than is usually thought, this should be kept up for a couple of weeks. In these capillary bronchitic conditions inhalations of oxygen are often of service, especially if the gas is administered by means of a large mouthpiece which covers both mouth and nose, as in the administration of ether.

For the prostration which so often accompanies grip, fluid extract of coca with nux vomica constitutes the best remedy. This prostration is the serious symptom of grip. Even with a slight influenza patients should go to bed and stay there. To continue on the feet may cost the patient his life even in mild cases Rest in bed is often quite enough treatment for the affection, but patients will insist on getting up, although their purpose may be no better than to go to a dancing-party and further spread the infection. It must not be forgotten that grip is as infectious as measles.

Anomalous Symptoms.—Dr. A. H. Smith said that while cases of influenza seem milder this year, some of them are associated with anomalous symptoms. He had just come from a case of mild grip in a young man, in whom, without any local reason, retention of urine had developed. Nearly a quart of urine was removed by catherization. Dr. Smith's experience has shown him the value of ergot in brow neuralgia. Some years ago, while acting as surgeon to the Brooklyn bridge builders, Dr. Smith had considerable experience with the painful symptoms which often accompany caisson disease. For these pains full doses of ergot acted like magic, while other analgesic remedies failed to give relief.

Prophylaxis of Grip.—Dr. Crooke said that not enough has been said about the prophylaxis of grip. Isolation of cases is, of course, not practicable. Certain individuals are, however, so susceptible to the disease, the young and the old, those with vulnerable organs, the tuberculous and the generally feeble and delicate, that they should be recommended to leave the infected district and go to a better climate. For this Florida is especially suitable. The elevated table-lands in the center of the peninsula make an ideal winter resort for such susceptible individuals. It would seem that quinine would act as a prophylactic against grip. If patients seem susceptible, that is, if they have had the disease several times before, four or five grains of quinine should be taken morning and evening during the existence of an epidemic. Stimulants are also important and a half an ounce of whisky may be advised if there seems special liability to grip, but this advice must be judiciously given. Physicians who are frequently exposed to contagion should often practise irrigation of the nose.

Treatment.—At the beginning of an attack of grip a mercurial or saline purge should be given if there seems to be any necessity, but not as a routine. If headache and pain are prominent symptoms five grains of phenacetin and twenty grains of sodium bromide should be given every five hours. Phenacetine seems to be specially applicable in grip and to be almost specific in its action against the pain. When fever asserts itself the following prescription may be employed:

℞ Dover's powder,.....
Quinine,.....
Acetanilid .....aa gr. ij

Two of these powders should be given at once and then one every three hours during the continuance of fever. If there is much excitement and restlessness a hypodermic of morphine should be given. The cough of grip is often as difficult to treat as that of whooping-cough. The following prescription has been found especially useful:

℞ Phenacetin ..... gr. ii
Codeine ..... gr. j-vj
Extr. glycyrrh. fl..... gr. j
Heroin..... gr. j-xxii

When the cough seems hard and hacking, muriate of ammonium, grains 3, should be given. In robust patients apomorphine, grain $^1/_{30}$, will be found of the greatest service. For the muscular pains which so often develop after grip and in which salicylates seem to do no good and give dyspepsia, Turkish baths will be found to furnish the greatest measure of relief.

Capillary Bronchitis and Counterirritation.—Dr. Morris Manges said that any one who makes

it a routine to examine the bases of the lungs will be amazed to find how often fine, dry râles occur at the end of expiration, often on both sides of the chest, the more frequently on the left at the very beginning of the disease. These râles mean a bronchiolitis of the smaller tubes. Atelectatic areas, from plugging of the bronchi, will be frequently found. For these symptoms counterirritation, especially the use of Priessnitz' bandage, is of great importance. It should be changed every four hours and it serves the very useful purpose of keeping patients in bed at times when they might otherwise insist on being up. For the cough heroin is an excellent remedy. Combined with terpene hydrate or potassium iodide it usually gives excellent results.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held January 1, 1901.

The President, Frederick Peterson, M.D., in the Chair.

Spinal Accessory Paralysis.—Dr. Pearce Bailey presented a man who last March had been operated upon for suppurating glands of the neck. During the operation the spinal accessory nerve had been cut. There had been immediate and complete paralysis of the sternomastoid and trapezius. About six weeks later the nerve had been sutured, with considerable improvement in the symptoms. During the past summer a weakness had appeared in the deltoid and in the muscles supplied by the musculospiral nerve. There had been considerable return of power. A fairly large incision had been made at the operation in the region of the mastoid. On inspection the shoulder on the affected side was seen to droop and the scapula hung away from the spine. The only anesthesia observed had been limited to the ear and over the right side of the face—an area corresponding to the supply of the great auricular nerve, which had undoubtedly been cut at the same time. There was now marked hyperesthesia over the distribution of this nerve. When first seen the position of the head had been slightly toward the injured side and a little downward.

Dr. E. D. Fisher suggested that there was a psychical element in the case. He said that on pressing along the muscles of the arm slowly there was no reaction, but if done suddenly there was a spasmodic contraction of the muscles of this region.

Dr. Joseph Collins did not think the whole condition had been explained by Dr. Bailey, for, in his opinion, there were symptoms of root involvement over a rather extended area. He could not understand how these could be explained by mere section of the spinal accessory nerve. The tic of the facial muscles and on either side of the neck and the narrowing of the palpebral fissure appeared to be associated with fibrillary twitchings. This would indicate a rather extensive involvement of the anterior roots in the cervical region. He would also like to know about the condition of the pupils.

Dr. F. Peterson said that he had seen this case before and had been interested in the complications. He had seen the man before the appearance of the twitchings, and on first noting the latter he had been inclined to assume that it was hysterical. However, after having made the electrical examination he had felt sure that it was not hysterical, but a pressure palsy involving a number of nerves, possibly as a result of sleeping with the arm in an upward position.

Dr. Bailey said that the suppurating gland had been situated deeply underneath the sternomastoid. When first seen by him last April there had been a typical picture of paralysis of the sternomastoid and trapezius, but no symptoms referable to the arm, no tics and no functional disorders. The man had been completely incapacitated for work, and this probably explained his psychical condition. The irritative condition of the face was probably explicable by the formation of new connective tissue in the scar. As soon as his attention had been called to the pressure palsy he had been watched at night and prevented from sleeping on his arm, and this had resulted in immediate and decided improvement. It was probable that in time the man would get fairly good use of his arm.

Facial Hemiatrophy.—Dr. Max Mailhouse presented a man, twenty years of age, without neurotic family history, who twenty-two months ago had a discoloration appear on the right side of the face below the lower lid. It had begun as a pale, depressed spot. When first seen by the speaker the right side of the face had been much atrophied and the beard had been absent on this side. The mouth had been drawn to the right and the right half of the tongue was much atrophied. The apparent prominence of the right eyeball was due to retraction of the lower lid. The hair of the right half of the scalp was grayer than on the left and was falling out. He had been losing his teeth on the right side. The nasal cartilage was wasted and its tip was turned to the right. The muscles of mastication were also atrophied, and this was associated with spasmodic pain. There was a fibrillary tremor of the large muscles. The affected muscles reacted feebly to faradization and normally to galvanism. No scleroderma was found. For the past two months there had been twitching of the muscles at the right angle of the mouth, and at times, after laughing, this angle would remain retracted. At such times there was a very tender spot in front of the ear. A blow of moderate severity had been received over the mouth ten years ago. No other etiological element could be elicited, and even this one seemed to have but little weight. The atrophy of the tongue seemed to be a strong argument for the theory that this affection is a trophoneurosis.

Dr. C. L. Dana said that he had met with several such cases and had found them all quite obscure. At one time the view had prevailed that it was a trophoneurosis due to some lesion of the

trophic root—a condition very difficult to understand. In one of his cases there had been a typical diffuse trigeminal neuritis, occurring in a woman of about forty years. The attack had begun with herpes and neuralgia and had been followed by a general neuralgia in the course of the fifth nerve. After this there had been atrophy and some anesthesia and, finally, a peculiar pitting of the face, like that from smallpox. In another case the trouble had begun, as it often did, with pigmented spots and neuralgia, and this had been followed by anesthesia in spots and a typical progressive anesthesia involving all the tissues, including the masseter muscle and the bone. In this patient there had been deafness and some disturbance of vision on the affected side. It was difficult to understand how a trophic or central lesion could cause all these symptoms. A herpes was almost always a sign of peripheral trouble. Another case had been that of a woman, who had married at the age of seventeen. Her husband had died, it was said, of syphilis a few years later, although the woman denied ever having become infected. She had had a progressive facial hemiatrophy for a number of years and had finally developed atrophy on the same side, affecting the arm and the leg. In none of his cases had there been anything indicating the true nature of the etiology. Perhaps the best explanation was that of a peripheral lesion as a starting-point. He had obtained no definite results from treatment, perhaps because he had not been able to keep these cases under treatment for a sufficient length of time. If the trouble were peripheral, Dercum's idea of resecting the trigeminus seemed to be worthy of consideration.

Dr. J. Fraenkel asked if any difference had been observed in the behavior of the sweat-glands on both sides of the face.

Dr. Mailhouse replied that there had been less sweating on the affected side.

Dr. Joseph Collins thought the disease could be explained just as well by a central as by a local lesion. He was inclined to think that the patient just presented had a lesion in the pons—in the area of central representation of the sympathetic nervous system in the pons. The lesion was probably a slowly progressive one, such as a gliomatosis. There already seemed to be involvement of the motor nuclei in the medulla oblongata. The enlargement of the pupil would be explained by an irritation of the sympathetic which had gone on to paralytic effects.

Progressive Lingual Hemiatrophy.—Dr. C. L. Dana presented in connection with the last case a rather rare form of progressive lingual hemiatrophy. It occurred in a man, twenty-six years of age, who had had the trouble three years, but had been otherwise in perfect health. The half of the tongue was slightly wasting away, and this was associated with fibrillary twitchings. The patient was a healthy young medical student without history of syphilitic infection or nervous heredity. It did not seem to him necessary to suppose that there was a gliosis, for Mendel has already shown that there is a change in the motor root of the trigeminus. Of course, these changes might be secondary to degeneration and partial destruction of the nerve.

Dr. Peterson said he was inclined to believe with Dr. Collins that some central lesion would best explain the condition. He had seen several cases, but all of them in a much earlier stage. In none of them had the tongue or the muscles of mastication been involved, nor had they presented the same pupillary phenomena.

Dr. Mailhouse thought the dilatation of the pupil might be explained by a similar process involving the sphincter pupillæ and causing weakness. Hoffmann had reported some improvement from the use of galvanism for half an hour daily.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Annual Meeting, Held at the New York Academy of Medicine, January 14, 1901.

The President, Robert F. Weir, M.D., in the Chair.

Operative Treatment of Umbilical Hernia.—Dr. Joseph A. Blake said that if early operations were done more frequently the results in this class of cases would be more satisfactory. The symptoms met with in umbilical hernias are of two kinds: (1) Those due to the size of the hernia and (2) those due to complications. Hernias which are irreducible on account of omental adhesions are exceeding common. If strangulation occurs, the prognosis is more grave than in inguinal or crural hernia. The statistics of operation are not of much practical service, because of the failure of surgeons to report unsuccessful cases, and because of defective methods employed. According to Bull and Coley, the mortality in irreducible umbilical hernia is 5 per cent., and in strangulated hernia about 60 per cent. Diagrams were presented showing the attenuated condition of the linea alba and the recti muscles. Dr. Blake briefly described the various procedures which had of late years been brought forward by different operators, such as the splitting of the sheaths of the muscles, etc. In speaking of the flap operation (in which the dorsal and ventral sheaths are both made use of), which was first described by Noble, of Philadelphia, in 1896, he said that the great objection was that when a sheath is removed from its muscle it loses its vitality. The operation to which Dr. Blake wished to call special attention was one of which he thought at first that he was the originator, but which he found had been described by both French and German surgeons, working independently of each other and who published their papers within one month of each other. Its main features are separate suture of the peritoneum, lapping of the recti muscles,

and suturing of the skin. The linea alba is excised above and below. Three different kinds of suture are employed, plain catgut, chromicized, and silkwormgut sutures. Stress is laid on the importance of cleansing all fat from the surfaces. The advantages claimed for the procedure are: (1) The durability of the abdominal wall at the hernial site; (2) the breaking of the lines of sutures; (3) broad surfaces for union. Dr. Blake has performed this operation with perfect success in three cases. Certain modifications were made in accordance with the special conditions existing in each instance. In the first case, that of a multiparous woman of thirty-eight years, with large abdomen and large hernial sac, only a portion of the sac was excised.

Dr. W. B. Coley said that most of the new methods brought forward have very few cases behind them. The one described by Dr. Blake certainly has many advantages, but also some disadvantages. Among the latter are the extensive dissection required, the danger of infection, and the risk of the operation. Prolonged etherization adds materially to the danger. At the same time, if this procedure has greater advantages, one can afford to take additional risks on this account. The main question to general practitioners in these cases is: Is any operation advisable? It was Dr. Coley's opinion that except by the most skilful operators and under the strictest aseptic conditions, no operation should be done. In nine cases of his own he had had nearly 50 per cent. of recurrences. As to whether a patient was better off after a recurrence than before the operation was performed, in his experience the condition was not improved. In one case in which there had been a recurrence one year after an operation by Dr. Bull, and a second recurrence, also within a year, after an operation by himself, the condition was worse than before. Up to the present time the Guzzoni operation had seemed to him the most rational, but he said he would be pleased to give Dr. Blake's method a trial and would hope for better results.

Dr. W. B. De Garmo said that he had always been somewhat at sea in regard to patients with umbilical hernia. Out of many hundred hernial operations performed by him there had been only sixteen for umbilical hernia, and in these cases he was forced to operate. On the whole, he believed now that he had been too conservative, and he was inclined to agree with Dr. Blake that one should not wait too long. He then made the statement that for several years he had been doing this very operation described by Dr. Blake, although he had never made any claim for priority in the matter. His method was not precisely the same in all respects, however, as that of Dr. Blake. In his later cases he had overlapped the abdominal wall without interfering with the peritoneum at all. He thought very favorably of overlapping, and, while he had formerly had about 50 per cent. of recurrences, his results had been better since adopting this plan.

Dr. E. Eliot, Jr., thought that there were some objections to Dr. Blake's operation, as well as a number of advantages in it. He did not see how one could approximate the aponeurotic fibers properly, and the best abdominal operators had always trusted more to the approximation of aponeurotic rather than muscular fibers. It seemed to him that the method was worthy of an extended trial in those cases in which it could be employed without putting the lateral portions of the abdominal wall on the stretch.

Dr. R. T. Morris said that Dr. Blake's method was mechanically attractive, but, from the experience in analogous cases, he was afraid that one would have to anticipate the following results: (1) A progressive thinning of the overlapping fibrous structures, unless the muscular structures should also be brought together. (2) Atrophy resulting from the line of traction of the rectus muscle producing absorption. In cases of diastasis he has been in the habit of taking out the linea alba, suturing the posterior sheath with the peritoneum, and then carrying the suture through the anterior, care being taken that the suture does not enter the fat.

Dr. Weir said that during the last five or six years he had had about a dozen operations. The hernial ring was cut out, the fascia approximated, and the layers sewn together, and the cases had done very well. In his experience he had found two forms of umbilical hernia. In the first there was a rather relaxed abdomen, and an operation was comparatively easy. In the other, with large omentum and abdomen and great tension, it was much more difficult. In some cases it was very difficult to make any overlapping whatever.

In closing the discussion Dr. Blake explained that the dissection involved was not extensive. The subcutaneous fat must be dissected off, but it can be done very quickly. As to the peritoneum, it can be left, if necessary. He did not claim this operation as a new one of his own, and was glad to hear that Dr. De Garmo had performed it successfully. The operation restored the muscles to their normal position; they were not changed in direction.

Cocaine Anesthesia in Eye Affections.—Dr. N. J. Hepburn said that cocaine had stood the test of time, and was still the standard by which other reputed local anesthetics were judged. It was not the object of the paper to speak of it in operations, but as a source of comfort to the patient in various painful affections. In these it was used as an adjuvant, but not to take the place of other remedial agents. It should be used in weak solutions (½ to 1 per cent.). If a 4-per-cent. solution was used it was apt to cause much subsequent suffering and to increase congestion. It was contraindicated in purulent and gonorrheal ophthalmia, and, in general, was of no service in affections of the deeper tissues of the eye.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held December 21, 1900.

Dr. L. W. Ely read a paper entitled "A Few Observations from the Lorenz Clinic," and Dr. H. L. Taylor a resumé of the treatment of Orthopedic Affections at Berck, France.

Reposition of the Congenitally-Dislocated Hip.—Dr. Ely, in a recent visit to Vienna, had spent some time in observing the practice of Lorenz, who was receiving cases of congenital dislocation of the hip from all parts of Europe. The cutting of tendons and instrumental traction were rarely seen. When the head of the bone had been replaced with suitable force and manipulation, the reduction was maintained by a most elaborately-applied plaster-of-Paris spica, which did not include the trunk and extended below only to the knee. The patient was then sent home to stay several months. The results were good and sometimes so brilliant as to justify the enthusiasm of the operator, who believed that when a knowledge of the operation was widely spread reduction would be made at such an early age as to almost preclude the possibility of a failure. The remarkable statistics of successes which had been published had their origin partly in enthusiasm and partly in the undoubted excellence of a method applied with requisite technic.

Dr. H. L. Taylor reported that the experience of Calot in his hospitals at Berck, on the channel coast of France, had showed that the bloodless reduction of congenital dislocation of the hip was applicable in children up to eight years of age, or later, in exceptional cases. Active treatment covered from six to twenty-two weeks and included two or three weeks traction with a weight of from ten to twenty pounds, and at the operation the application of a force of 300 pounds for ten minutes to bring the head of the bone down to or below the acetabulum. When the retaining apparatus was removed massage and training in walking completed the treatment. Patients had recovered without the trace of a limp. He had practically given up the open method. The correct attitude obtained by cutting would be at the expense of limitation of motion or ankylosis, which might be properly sought by this method in certain cases in which replacement was impossible.

Dr. R. H. Sayre had seen Lorenz operate last year in Paris at the Redard clinic. The patient, a child of about eight years of age, was moderately disabled by a single dislocation of the hip. The thigh was made to form an angle of perhaps 20 degrees posterior to the plane of the body. A great amount of force was employed for this and in turning the limb in various directions. The head of the femur could be heard as it popped around on the ilium in what must have been a mass of lacerated tissues. The spica, which was nearly two inches thick where the strain came, included two loose strings for subsequent use in scratching the skin and keeping it clean. The head did not assume a permanent residence in the acetabulum. It was said that it would do so after the child had walked about for a year or two in the spica, a question which would have to be answered in due time.

Dr. C. H. Jaeger had recently spent six weeks at Vienna and reported that the treatment of congenital dislocation at the Lorenz clinic was exclusively by the bloodless method. Double cases were treated singly. The results were very favorable. The spica was applied with great care. Only a thin layer of cotton padding was used. The plaster bandage was applied very snugly, the thigh only being enclosed and a narrow strip going about the pelvis. This left the knee and ankle free and also the whole spinal column. The limb being thus fixed in extension and abduction, the patient soon learned to walk without crutches and with (in single cases) a high sole on the sick foot. It was most interesting to see a child with double dislocation, with both legs strongly abducted, spread eagle fashion, walking beautifully, hopping with one leg, then the other without a stick or help of any kind. Lorenz was accustomed to lay great weight on having the parents of the patient extend the knee many times daily, to prevent contracture. In opposition to these views Hoffa strongly advocated the open method.

Dr. W. R. Townsend said that Hoffa had stated in very positive terms that none other than the bloody operation could be of any use. An American authority also had reported that in a large number of open operations only two or three had exposed an acetabulum in which it was possible to place the head. The views and practice of Lorenz, however, were those of one whose experience with the open operation had been greater than that of all other operators combined.

In one of the dissections reported by Dr. E. H. Bradford the capsule had been found pushed in front of the head of the bone in such a manner that a perfect reduction could not be made. This had led to the suggestion that in some cases the open operation might be modified by slitting the capsule instead of gouging or boring the bone which might lead to ankylosis or limited motion.

Dr. Jaeger thought that Hoffa was dissatisfied with the bloodless procedure partly because of the position in which he fixed the limb after reduction of the deformity. He applied the spica with the limb in extension and strong inward rotation, which could not afford a very firm hold for the femoral head in the acetabulum. In this position it was probable that reluxation would occur during the application of the bandage or on the first attempt at walking.

Dr. G. R. Elliott had passed several weeks with Lorenz in 1896 and had seen him operate

many times by the non-cutting method, having already begun to discredit the cutting operation, which he had done so much to perfect. There could be no possible doubt of the good results obtained. He had seen many instances and had repeated them in his own practice. Success lay in the thoroughness of the procedure and in the perfection of the technic. (1) The head of the bone should be brought down to the level of the acetabulum. (2) It should be lifted over the posterior edge of the acetabulum. (3) Abduction should be extreme, even posterior to the mid-plane of the body. (4) The plaster bandage should be pressed posteriorly against the joint to keep the reduced head from slipping backward. Great force was often required, but neglect of any point would leave the head of the femur resting on the posterior acetabular edge to be dislocated as soon as the bandage was removed. Lack of success would be due to want of technic leading to imperfect reduction. Thorough padding was necessary beneath the bandage. Blood had appeared in the urine of a patient operated on by him last week. The child had been laid face downward to facilitate fortifying the splint posteriorly and the soft plaster bandage had pressed against the abdomen and hardened. Cutting the bandage relieved pressure and the blood disappeared.

Sea-Air for Tuberculous and Rickety Patients.—Dr. Taylor, in his review of the treatment at Berck, said that Calot was an enthusiastic advocate of sea-air for patients affected with external or peripheral tuberculous lesions, those of the skin, glands, bones and joints. He rejected phosphorus in the treatment of rickets, prescribing intestinal antiseptics and a diet mainly of milk and eggs. Many of his patients were kept recumbent. He affirmed that rickety deformities would disappear during a sojourn at the seaside.

Dr. Sayre had listened to Calot as he described the advantages of seaside treatment. His interest in the subject was shared by others of his countrymen, whose native enthusiasm perhaps lent a too rose-colored light to their views.

Dr. Taylor had been impressed with the picturesque quality of Calot's writings. His zeal often broke through the conventional boundaries of scientific composition. The reader was entertained and delighted but not necessarily convinced.

Treatment of Pott's Disease.—Dr. Ely said that Lorenz used a corset composed of perforated strips of celluloid, metal bands and canvas. It laced in front and was probably sufficiently comfortable, but could not be said to "splint the spine."

Dr Taylor said that although Calot declared that neither braces, plaster jackets nor corsets could prevent or arrest the deformity, all of his patients wore the plaster jacket after subjection to manual pressure directed against the kyphos. In certain cases ablation of the spinous processes without invasion of the tuberculous territory was recommended in order to facilitate correction and avoid sores from pressure of the jacket. The use of suspension, the amount of manual pressure and the degree of lordosis to be enforced were points to be settled for each case. Severe pressure and all traumatisms were to be carefully avoided, in marked contrast with the violent proceedings which called attention to the name of Calot in 1896, when he was claiming uniformly-brilliant results from the outlay of all his strength on the kyphos, supplemented with cuneiform resections in obstinate cases.

Dr. Sayre said that Calot's recent methods, as he had heard him describe them, varied but little from those of Dr. L. A. Sayre when he introduced suspension and plaster-of-Paris jackets. Calot had, however, secured a distinct advantage in extending the jacket up to the chin instead of stopping at the top of the sternum, thus promoting lordosis even of the lumbar spine and gaining a leverage over the entire spine which was impossible when the upper part of the vertebral column was free.

Treatment of Joint Diseases.—Dr. Ely said that at the Lorenz clinic joint diseases generally were treated by retention in plaster of Paris. The spica for hip-disease usually had an iron stirrup running down from the bottom to take up the weight of the body.

Dr. Taylor said that Calot very justly believed that a stiff joint in a good position was better than a movable joint in a bad position. It was his practice to reduce the deformity by force and retain the improvement with a plaster spica. Complete anchylosis in a bad position required subcutaneous osteotomy of the femoral neck.

Treatment of Abscesses.—Dr. Jaeger had noticed fewer abscesses in patients affected with hip-disease at Vienna than in patients of the same kind in America, which was not easy to explain except by climatic differences, as the poor there were poorer, and their nourishment probably worse than in this country.

Dr. Taylor said that Calot forbade incision, curetting and excision in Pott's and hip-disease, unless the joint or abscess was infected or a sequestrum was found. He took the ground that patients affected with these diseases practically always got well under closed treatment and always died under the open treatment. Abscesses were to be treated by roborant drugs, a full diet, correct hygiene and rest. A cold abscess might be aspirated through healthy tissue and medicated by injections. By repeated aspirations and the application of compresses and bandages openings which seemed inevitable might be averted and in from four to eight weeks the abscess would disappear without a scar and with healing of the bone in most cases. It was interesting to note that we had (1) in Calot a surgeon of ten years active experience, formerly an advocate of scraping, incisions and excisions, with the reputation of having done

80 excisions of the hip, who was now aggressively opposed to the operative treatment of diseases of the joints, and (2) in Lorenz a surgeon of great experience in the cutting treatment of congenital dislocation of the hip who had given it up in favor of a bloodless method. The coincidence and the contrast between the recent past and the present were quite impressive.

Lateral Curvature from Division of the Spinal Accessory Nerve.—Dr. R. A. Hibbs related a case as follows: A girl, fourteen years old, had had glands removed from the left side of the neck six months before she was first seen a few days ago. There was spinal curvature toward the right with drooping of the left shoulder, paralysis and atrophy of the trapezius and marked disability of the left arm. The patient declined an operation for uniting the ends of the spinal accessory nerve, which had evidently been severed at the point where it pierced the sternocleidomastoid muscle.

Dr. Myers recalled the case of a similar patient, fifteen years of age, whom he had been observing for three or four years. He saw her eighteen months after the paralysis, and considerable permanent atrophy of the muscles of the shoulder had set in. There was spinal curvature toward the opposite side which did not go on to be extreme and was easily controlled.

Fracture of Cervical Vertebræ.—Dr. Sayre related the case of a man who was carried home unconscious after a fall on the head and neck about two months ago. On regaining consciousness there was paralysis of the extremities, bladder and rectum, in which there was slow improvement after two days. As every attempt to walk increased his symptoms he was kept in bed several weeks. A diagnosis of fracture and dislocation of the fifth and sixth cervical vertebræ was made on his history, the flexion of the head, the absence of motion of the head and neck, difficulty in swallowing and the disability of the left upper extremity. The diagnosis was confirmed by skiagraphs, of which it had been necessary to take several from different points of view. One of the negatives was taken after fastening a bandage tightly over one shoulder and under the opposite arm-pit so as to make a gulch in which one edge of the plate had been forced as far as it would go. The skiagraphs and a brace were exhibited. The latter consisted of a leather and steel collar attached to posterior steel rods and a pelvis belt. The head and neck would be thus fixed until consolidation was assured, the brace being capable of easy modification from time to time as the patient improved. He recalled an almost exact counterpart in a case which occurred several years ago in which the application of a jacket and jury-mast had been followed by disappearance of the paralysis.

Pneumatic Perineal Straps.—Dr. Myers exhibited rubber tubes, 10 inches long and 1¼ inches in diameter, designed to take the place of the ordinary perineal straps. Smaller sizes were also made. Each tube was provided with a removable cover of canton flannel and a valve for inflation by a bicycle pump. The straps were not elastic. They were expensive, but very durable. The pressure made by them was equalized automatically and that made them especially comfortable for older children and adults whose weight made perineal support difficult.

BOOK REVIEWS.

Text-Book of the Embryology of Invertebrates. By Drs. E. Korschelt and K. Heider. Vol. IV. Higher Invertebrates. The Macmillan Co., New York.

We have referred in an earlier review of the three preceding volumes to the classical value of this Embryology. It is pleasing to have the work completed in the excellent manner in which it began and students of zöology are to be congratulated on having this excellent volume in English.

Essentials of Histology. By Louis Leroy, B.S., M.D., Professor of Histology and Pathology in the Vanderbilt University, Medical and Dental Departments, etc. 1900. W. B. Saunders & Company, Philadelphia.

This little book contains within a limited space and in a convenient form the essential facts relating to histology. Naturally enough nothing new has been found. The book is merely an epitome of more comprehensive texts. Each section is followed by a series of questions, the mastery of which insures knowledge of the salient points of the subject discussed. As far as it goes the text is reliable.

Progressive Medicine. A Quarterly Digest of Advances in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D. Volume IV. December, 1900. Lea Brothers & Co., Philadelphia and New York, 1900.

The present volume of "Progressive Medicine" contains a review of the diseases of the digestive tract and allied organs, the liver, pancreas and peritoneum, by Max Einhorn, M.D.; genito-urinary diseases and syphilis, by William T. Belfield, M.D.; fractures, dislocations, amputations, surgery of the extremities and orthopedics, by Joseph C. Bloodgood, M.D.; diseases of the kidneys, by John Rose Bradford, M.D.; physiology, by Albert P. Brubaker, M.D.; hygiene, by Henry B. Baker, M.D., and a practical therapeutic referendum, by E. Q. Thornton, M.D.

Dr. Einhorn is a recent addition to Dr. Hare's corps of subeditors. His first article, on diseases of the digestive tract, shows that the readers of "Progressive Medicine" are to be especially well cared for in the matter of being kept up to date in gastro-intestinal nosology. There are discussions of the test-meal, of the gastric douche with double current, of the stomach powder-blower, and of molds in the stomach, that are of particular in-

terest to the stomach specialist. There is a very interesting review of the symptomatology of pancreatic disease. The following shows how practically our knowledge of diseases the pancreas is developing: "The attack which culminates in pancreatitis is often one of several, not differing in its inception from others already recovered from, except in its severity and persistence. This is particularly the case with alcoholics, who are exceedingly fond of calling themselves 'bilious' (whatever that may mean) and taking their blue mass to get straightened out from their indiscretion."

In the chapter on surgery of the extremities and orthopedics there is a very interesting review of the recent literature of gonorrheal arthritis which shows how much additional significance has accrued to this disease in recent years. In the chapter on diseases of the kidneys there is a very suggestive discussion of the relation of Bright's disease to syphilis. The question of prescribing mercury, even in the form of a purge, to patients suffering from renal disease, is taken up. Far from being considered harmful, as some claim, mercurial salts are set down as ideally beneficial in many of these cases, because of their purgative and slightly diuretic action.

The practical therapeutic referendum contains a series of prescriptions with discussion of their merits and mode of administration, and shows what new drugs have recently proved worthy of attention and how they can be best prescribed. It constitutes a valuable reference for the busy practitioner who hears of new drugs through the trade and wonders what their real clinical and scientific value may be.

A Text-Book Upon the Pathogenic Bacteria for Students of Medicine and Physicians. By Joseph McFarland, M.D., Professor of Pathology in the Medico-Chirurgical College, Philadelphia; Pathologist to the Medico-Chirurgical Hospital, Philadelphia. Third Edition. W. B. Saunders & Company, Philadelphia.

The problem of insistent revision is ever presenting itself to those who have written on medical topics; in no subject is this more conspicuous than in the subject of bacteriology. The gradual but steady specialization that has taken place in the science, especially in relation to the public health and industries, has given us so much information on many themes that newer editions must perforce be brought to meet the demands of shifting and newer positions. Dr. McFarland has done his part so conscientiously that his book has met with corresponding success. Coming from a careful man, who has had such great experience, this was to be expected.

This edition has been considerably revised, and is chiefly characterized by a more consistent and uniform general treatment. Suppuration, from a purely bacteriological point of view, is well treated for the purposes of the student and physician. The chapter on tuberculosis is excellent; we are surprised, however, to still find that the Hirschfelder oxytuberculine has been retained. Facts do not warrant this. The article on diphtheria is one of the best in the book and clearly sums up in a concise form our present views on this very important disease. The other sections are equally good. We further congratulate the author for his wisdom in introducing that important section on the standardization of media, so ably advocated by George W. Fuller (not Tuller) in 1895 and since urged by the Committee of Bacteriologists of the American Public Health Association.

We unreservedly recommend this book to those seeking general bacteriological information; its treatment is sufficiently flexible to appeal to both students and physicians.

A Manual of Surgical Treatment. By W. Watson Cheyne, M.B., F.R.C.S., F.R.S., Professor of Surgery in King's College, London, and F. F. Burghard, M.D., and M.S. (Lond.), F.R.C.S., Teacher of Practical Surgery in King's College, London. Volume IV. The Treatment of the Surgical Affections of the Joints (Including Excisions) and the Spine. Lea Brothers & Co., Philadelphia and New York.

The fourth volume of this thorough and excellent manual deals with the surgery of the joints. Dislocations, sprains and wounds are first considered. The diseases of joints in general, followed by those in particular, are next considered. The volume closes with the spinal diseases of surgical import—injuries, spina bifida, kyphosis and scoliosis, tuberculous disease and tumors.

Under the treatment of sprains, no mention of the ambulatory method is made. The authors recommend, however, early and continued massage, the injured member meanwhile being encased in a light splint.

The various methods of diagnosis and well-known forms of treatment of the different dislocations are given in detail. Perhaps the best chapter in the volume is the one on articular tuberculosis which is a splendidly-condensed epitome of present-day knowledge on the subject. Orthopedic appliances are fully described and in an appendix is given an elaborate series of "medical gymnastic exercises" well illustrated. Spina bifida is treated either by injection or by operation, the indications for each method being described.

Altogether this volume forms a fitting companion to its predecessors, although, contrary to their rule, several operative procedures are here described by the authors.

VERATRUM VIRIDE; ITS VALUE IN SOME CONDITIONS OF TOXEMIA.[1]

BY A. B. ISHAM, M.D.,
OF CINCINNATI.

IN the medicine of to-day veratrum viride finds but limited employment. The traditions and writings of the "Fathers" are yet sufficiently regarded, however, outside of the medical centers to maintain for this drug a place in the armamentarium of most country practitioners. But, since the advent of pilocarpine, the teachers of materia medica and of therapeutics have given veratrum viride such scant consideration that the physicians of the past fifteen years, particularly in cities, are practically unacquainted with the virtues of this potent medicinal agent. Of four drug-stores in Clifton and Mt. Auburn to which a prescription for Norwood's tincture was sent, a short time since, only one had a supply of the preparation. At the others it was said that there had never before been a call for it.

Perhaps, however, the object of this endeavor may be better pursued by eschewing verbiage and furnishing instead a series of clinical illustrations in the form of case reports. The six cases to follow are all of peritonitis, without exception undoubtedly having origin in appendicitis. The number does not, by any means, exhaust all cases of the same character coming under observation, but six cases afford, in the newspaper vernacular, "sufficient evidence of good faith," and the others are reserved as "not necessarily for publication." It is presumed that the cases are germane to the caption of the paper, and that it is not requisite here to argue that a state of toxemia exists with peritonitis.

Case I.—W. B., American, married, aged forty-two years, was seen June 30, 1876. Had pain in right iliac region, radiating over abdomen, of a paroxysmal nature, pulse 100, temperature, 100.2° F. Tenderness and tumefaction in right iliac region. Had suffered slight pain, with tenderness upon deep pressure, for several days, together with constipation. Free action of the bowels was obtained through the administration of calomel and salts and the use of enemas. The abdomen was generally tender to pressure, but soft, except in the right iliac region. There was pain, increasing during the night, and hypodermatic injections of morphine were given with relief. July 1st, general abdominal pain, distention and hardness; pulse, 120; temperature, 104° F.; delirium. Diagnosis, perityphlitis and general peritonitis. Treatment, veratrum viride, eight drops, every two hours, and hot turpentine stupes. The veratrum was continued in eight-drop doses until free perspiration and nausea occurred, together with a lowering of the pulse-rate, when the dose was reduced to four drops every two or three hours. Free diaphoresis took place during the night. By the morning of July 2d the pulse was reduced to 68; temperature 100.5° F.; the abdomen was less tumid and tender, there was still nausea, the skin was moist, and, while the patient was somnolent, there was no delirium. In fact all the evidences of resolution were at hand, which progressed steadily until the 8th, when he was discharged convalescent. There was still some induration in the right iliac region, with slight tenderness. He never had any further abdominal trouble and is alive and well to-day.

Case II.—G. K., American, widower, aged twenty-seven years, was seized with severe pain over the abdomen the night of April 21, 1880, which was relieved by hypodermatic injection of morphine and he rested through the night. On the 22d his pulse was 96; temperature 101° F. There was some induration in right iliac region, with tenderness. Bowels were thoroughly emptied by calomel, salts and enemas. In the evening the pulse was 110; temperature, 102.5° F.; some distention of abdomen and general tenderness over it, which increased until on the morning of the 23d the pulse was 125 and temperature 104.5° F. The abdomen was tumid and hard and there was delirium. The veratrum viride was given as in the former case and hot turpentine stupes were employed. The diagnosis was perityphlitis and general peritonitis. On this day—the 23d—Dr. Reamy and the late Dr. Keyt saw the case in consultation and concurred in the diagnosis and treatment. By the morning of the 24th satisfactory evidences of resolution were present in a lowering of pulse and temperature, less tumefaction of the abdomen, and a restoration to consciousness. The patient recovered slowly and was discharged convalescent May 23d. At that time there was still some induration and tenderness in the right iliac region. This eventuated in an abscess which was incised September 23, 1880, and exit given to about two ounces of fetid pus. The opening discharged for a week and then healed. There has been no trouble since, except that about five years ago he suffered an oblique inguinal hernia at the site of the incision.

Case III.—Mrs. E. T., American, widow, aged seventy-two years, first seen November 16, 1886. Paroxysmal pain over abdomen, more marked in right iliac region, where there was a small induration. Had been constipated. Pulse, 84;

[1] Read before the Academy of Medicine, Cincinnati, December 3, 1900.

temperature, 99.5° F. Bowels were completely evacuated with calomel, salts and enemas. On the 17th pain was increased, more marked tenderness over abdomen, which was everywhere distended and tympanitic. Pulse, 118; temperature, 103° F.; wild delirium. Diagnosis, perityphlitis and general peritonitis. Veratrum viride and hot turpentine stupes were employed as in the previous cases. By the 18th resolution was well established. After this, while she had no active febrile condition or noteworthy disturbance, she remained completely helpless and did not gain strength. On the 29th she began to have slight rigors, followed by perspiration. The skin in the right iliac region above Poupart's ligament was then noticed to be puffy and edematous; there was quite an area of dulness and tumefaction in this locality and it was apparent that an abscess was forming. On the 30th Dr. N. P. Dandridge was called in consultation. By careful dissection he opened, but did not expose, the abscess cavity, from which a half pint of most offensive pus was evacuated. This continued to discharge for about a week, and in two weeks was entirely healed. December 17th she was discharged convalescent. She never had any other abdominal trouble, except hernia, and died in her eighty-fourth year from cerebral hemorrhage.

Case IV.—Mrs. M., American, married, twenty-two years of age, was confined with her first child November 3, 1894, and was safely delivered of a vigorous male child, after an unusually difficult forceps delivery. She seemed but little affected by the severe experience, and attendance upon her ceased on the 16th, at which time she was in all respects perfectly normal, and she was left in the care of a trained nurse from Christ's Hospital. Was called again to see her on the 24th, when it was found that the nurse had permitted her to go without a movement of the bowels for seven days. She was in great distress, abdomen distended, lumpy and tender, particularly in the right iliac region. The temperature ranged between 100° and 102° F.; the pulse varied from 96 to 120. It was not before the 27th, by the use of oil, calomel, salts, all forms of enemas and high injections, that the intestinal canal was satisfactorily evacuated. By this time a general peritonitis was in full flower, which was treated as in the other cases reported and with the same success, so that by the 29th resolution was well established. She was discharged convalescent January 1, 1895. At that time an induration as large as a walnut yet remained on the right side in a line drawn from the superior iliac spine to the umbilicus, which was tender upon pressure. It wholly disappeared after the lapse of several months, but she had relapses of pain and tenderness, accompanying constipation at irregular intervals of two, three or four months, and only within the past two years has she ceased to have any disturbance therefrom.

Case V.—B. O., American, aged fourteen years, an unusually large, stout girl for her age, was seized with severe abdominal pain November 27, 1899. She had not been feeling well for several days, having no desire for food and complaining of spasmodic pain, of light character, over the abdomen. Bowels inactive; slight tumefaction in right inguinal region. Calomel, rhubarb and salts produced free liquid stools, and hot fermentations were employed for relief of pain. Notwithstanding, a high grade of peritonitis was set up the night of the 28th, with violent delirium and a temperature reaching at the highest 105° F. The veratrum viride and hot turpentine stupes formed the treatment, as in the preceding cases, and after four days of anxious ministrations it was a supreme satisfaction to have resolution inaugurated on December 2d. She was discharged convalescent on the 10th. At that time there remained some induration in the right iliac region, and tenderness upon deep pressure. This wholly disappeared in the course of a month.

Case VI.—J. O'C., American, married, aged twenty-seven years, was seen in consultation with Dr. A. C. Poole May 22, 1900. Dr. Poole had been called to him the previous evening by reason of his suffering from severe abdominal pain, for which morphine was hypodermatically injected with relief. Condition at the consultation: Abdomen greatly distended, hard, tender, more particularly in right iliac region, where there was a feeling of induration. Patient said that he had taken cold from exposure in the Fire Department and that his bowels had been torpid. Temperature, 103.8° F.; pulse, 125; restless and clamorous for relief; semi-delirious. Diagnosis, general peritonitis and probable appendicitis. At Dr. Poole's request I assumed charge of the case. Free action of the bowels was induced by calomel, salts and enemas, and veratrum viride and hot turpentine stupes were employed. To show the unpromising nature of the case it may be narrated, upon the authority of Dr. Poole and the people of the house, that a surgeon, who had been called in consultation earlier in the morning, had advised removal to a hospital and immediate operation as the only chance for the patient's life. As a result of the means instituted resolution was well advanced on the 24th, and June 10th he was discharged convalescent, at which time there was some tumefaction in the right iliac region, although no marked induration. He has since been perfectly well in all respects and is now doing duty in the City Fire Department.

In all the cases it will be noted that there existed at the commencement a condition of obstipation. With a torpid and distended bowel, there must necessarily occur a change in its relative position to the appendix, as well as a variation in the form and size of the appendical opening into the intestine. It is conceivable under such circumstances that products of fermentation or decomposition might find entrance into the appendix, set up a catarrhal inflamma-

tion, and toxins be developed through the influence of pathogenic organisms. These may be neutralized by alexins and no damage result; or plastic lymph may be formed, walling in the appendix, local abscess may ensue, finding exit either into the bowel or externally, with sloughing off of the appendix, after which healing takes place and all is right again, with the exception of the adhesions that have formed during the process. Yet again, as in the series of cases presented, the septic material formed passes over into the absorbents in the peritoneum and a general peritonitis lights up, which may not stop short of a general infection. Particularly may the muscular substance of the heart rapidly undergo pathological alterations and death ensue with astounding suddenness. This may even obtain when there has been no sign of toxemia, no peritonitis, no general infection and when the temperature and pulse have followed nearly the normal standard for days.

Another form of toxemia is now to be offered for consideration in the way of a series of clinical histories:

Case I.—Mrs. B. S., German, widow, aged seventy-three years, was seized with convulsions December 28, 1891. She was unconscious, had stertorous breathing, pulse 126, of moderate force and volume. Temperature was not obtained. The catheter was passed and a tablespoonful of urine, which was slightly albuminous was secured. Suppression of urine. Injected twenty-five drops of veratrum viride hypodermatically. Then followed within half an hour free perspiration, salivation and vomiting of bile. Consciousness returned within an hour, when temperature was normal and pulse 66. She was sitting up next day apparently well, but weak. She is still living and in good health at the age of eighty-four years.

Case II.—Mrs. B., colored, married, fifty years of age. Was seized with convulsions in night of August 27, 1894. At time of my visit she was unconscious, breathing stertorously. Temperature, 103° F.; pulse, rapid, full and bounding. Twenty-five drops of veratrum viride were administered hypodermatically. In an hour temperature was reduced to normal, and there was free perspiration and retching of bile; pulse, 70; sleeping quietly. Was engaged in her domestic duties on the 29th.

Case III.—K. G., infant, nine months of age, had been ill with enterocolitis since March 12, 1897. It had become greatly emaciated, when it was taken with carpopedal spasms March 23, 1897. There was complete unconsciousness. Temperature 104° F. Twelve drops of veratrum viride were at once injected hypodermatically. It promptly reduced the temperature, producing diaphoresis and vomiting of bile. Consciousness was soon restored. During the intervals of retching the child slept peacefully, perfectly relaxed. It was afterward able to retain and assimilate nourishment and complete recovery was established.

Case IV.—J. B., married, Scotch-Irish, seventy-three years of age. Had enlarged prostate with retention of urine occasionally, for which it had been necessary to catheterize him at various times. On September 11, 1897, which was an exceedingly hot sultry day, with the atmospheric temperature at 96° F., he suddenly became unconscious and slight spasmodic movements of the arms and legs occurred. When reached he was wholly unconscious, quiescent, breathing stertorously—with Cheyne-Stokes respiration—and had passed feces in bed. Pulse, 132, full and bounding; temperature, 105.5° F.; urine suppressed. Catheterization obtained little more than a teaspoonful; no albumin. It was considered a case of heat-stroke with uremia. Thirty drops of veratrum viride were injected hypodermatically. Within half an hour the temperature was reduced to 100.5° F., and the pulse to 84. Consciousness returned within an hour. As in the other cases there was copious perspiration and salivation, with free vomiting of bile. Discharged convalescent September 15th. He had another similar experience June 27, 1898, when the atmospheric temperature was "well up in the nineties." This time the temperature in the axilla was 105° F. Twenty-five drops of veratrum viride were hypodermatically injected with the same good effect as before. The body temperature went up again on the two succeeding days and the hypodermic injections of veratrum were repeated with the same result. Discharged convalescent July 6th. He died April 2, 1900, of secondary nephritis consequent upon the prostatic enlargement and catheterization.

Case V.—B. W., American, married, aged sixty-five years, a very stout man, was seized with convulsions April 12, 1898. He was found unconscious and with stertorous breathing. Pulse was rapid and weak; temperature, 100° F. Sample of urine obtained next day of normal reaction. Injected hypodermatically twenty-five drops of veratrum viride. This was followed by free perspiration and retching of bile, and return to consciousness ensued in due time. Next day was attending to his ordinary duties. Died suddenly March 23, 1899. Was taken with a chill in a street-car and just as he reached his home, he expired with all the symptoms of pulmonary engorgement.

Case VI.—Mrs. O., American, widow, aged sixty-two years, was visited the night of July 16, 1900. She had been seized with convulsions of face and arms of moderate severity. Was delirious, rolling about in the bed; pupils somewhat dilated, with a wild and staring appearance of eyes. Temperature, 101.4° F.; pulse, feeble and frequent. Twenty-five drops of veratrum viride were injected hypodermatically. Free perspiration, salivation and retching of bile ensued with restoration to consciousness and restfulness.

To the above may be appended a case of different character, yet nevertheless one of toxemia induced by pneumococci.

Case VII.—J. G., a vigorous man, eighty years of age, was taken with severe pain in lower, anterior portion of right chest the evening of March 17, 1900. He had a loud, blowing, systolic murmur, most accentuated at apex of heart, but generally diffused, which had existed for some time and which, in all likelihood, was due to calcareous deposits upon the edges of the mitral valves. He was breathing rapidly and with difficulty, had a short, hacking cough, was semi-delirious, and constantly insisted on getting out of bed. Temperature, 102.6° F.; pulse, 120. There was dulness on percussion over a circumscribed portion of the lower lobe of the right lung anteriorly, and fine crepitation corresponding to the area of dulness. He had passed freely urine of normal reaction. Twenty-five drops of veratrum viride were injected hypodermatically. Free perspiration, salivation and retching of bile followed in due order. The temperature fell to 99° F. and the pulse to 58. Pain and delirium ceased and he rested easily the balance of the night. The temperature showing a tendency to rise next day, the veratrum was exhibited by mouth in four-drop doses every two hours. The cough loosened and there was expectoration of streaked mucus. He progressed steadily and was discharged convalescent March 21st, after an illness of five days.

Another case is added because it may possibly have been one of toxemia, although I regard it as one of gastralgia and hysteria in the male.

Case VIII.—J. S., American, aged twenty-eight years, widower, lost his wife last January in Frankfort, Ky., from puerpural convulsions. He had convulsions himself at the time of her death. Subsequently he removed to Portsmouth, Ohio, where he had several attacks of convulsions. He was considered in grave danger of losing his life each time and recovery was slow. Was treated each time by morphine hypodermically. I saw him July 13, 1900, in tonic convulsions, so that it required the utmost efforts of two strong men to hold him on the bed. He was apparently unconscious. I learned that he had eaten a hearty supper of boiled beef, cabbage, dumplings and Swiss cheese. Upon retracting the lids the pupils were normal and the balls were rolled upward and inward to avoid the light. Thirty drops of veratrum viride were injected hypodermatically. In a few minutes his stomach was emptied of an enormous quantity of material. Free perspiration and salivation followed, with continued retching of bile; consciousness returned. There were no more convulsions and he rested quietly through the night. The next day he was able to sit up, but was sore from the muscular exertion of the night before. He was given directions as to diet, a dissertation upon the efficacy of will power in controlling reflexes, and was told to take one ounce of linseed oil twice daily—morning and evening. He has remained well since. In this connection the suggestion arises that veratrum viride may prove a valuable agent, on account of its relaxing properties, in gastralgia from muscular spasm of the stomach pylorus, and in cases of hepatic colic from the passage of gall-stones through the ducts. By its employment in such conditions one may possibly dispense entirely with the use of morphine hypodermatically.

The knotty problem of elucidating the *modus operandi* by virtue of which this drug is enabled to display its beneficial attributes, now presents itself. After its administration the effects first observed are referable to the glandular system. The sudoriferous glands are excited to activity, the skin becomes bathed with sweat, and in some cases it is poured out over the whole surface of the body in such quantity that the patient appears to have been drenched with water. The salivary glands also pour out their secretion abundantly and there is drooling from the mouth; sometimes, however, when there is most copious perspiration, salivation is not prominent. In all cases there is vomiting or retching of bile, and the quantity of this fluid brought up in many instances is so great as to preclude the idea that it is simply the contents of the gall-bladder which has undergone evacuation through the stomach by way of the intestine. The capacity of the gall-bladder is stated not to exceed an ounce and a half, and more than this quantity of fluid has been observed to be ejected in a single effort at retching, after all the residual contents of the gall-bladder and stomach must have been expelled. The cells of the liver are undoubtedly excited to greatly increased activity through a direct action of the drug upon them. This excitation of the salivary and sweat-glands has been ascribed by investigators to vasomotor paralysis and consequent decrease in pressure in the peripheral blood-vessels, but there is never noted such an outpouring of fluids in cases of spinal injury with apparently complete vasomotor paralysis. In addition to this vasomotor influence, there must be some excitatory action of the drug upon the gland-cell. In the case of jaborandi, a congener of veratrum viride, H. C. Wood, Jr.,[1] admits as probable a special action upon the salivary gland-cells, which he does not accept for the latter agent. For all the evidence adduced to the contrary by experimenters, in the light of clinical observation we may claim that veratrum viride, in addition to its effects upon vasomotor functions, exerts some stimulating influence on the cells of the liver, salivary and sweat-glands.

These glandular phenomena have a therapeutic significance not to be passed over lightly. The activity of the salivary glands is, perhaps, of much less importance in toxemias than that of either the liver or sweat-glands. But we know that the salivary glands take up toxic substances from the system which are excreted by the mouth and that potassium sulphocyanide is contained constantly in the secretions, elaborated from the blood by the cells within the glands, showing that they possess within themselves a power of trans-

[1] Therapeutics, Materia Medica and Toxicology, Third Edition, p. 514.

formation upon materials recognized as poisons. These properties of the salivary organs, under the stimulus of the green hellebore, may exercise a very considerable power in neutralizing and removing leucomaines and toxins.

The liver is the largest glandular organ of the body. It was long ago determined that one of ..nctions was the destruction, within its substance, of matters inimical to the organism. Concerning the method by which this is accomplished there is no definite information. When the position of the liver is considered, its large size, its nearness to all the organs concerned in digestion and blood-formation, stimulation of its energies, as by veratrum viride, to many times the normal value of its work must greatly increase its efficiency in disposing of toxic material brought to it from the abdomen by the portal vein and from all over the system by the hepatic artery. It is a factor in the conservation of life under conditions of toxemia of no secondary value. The retching and vomiting induced by the drug also indirectly spur up the liver to increased secretion, through muscular action and siphonage. It is likewise, undoubtedly, indicative of a hyperactivity of the cells of the stomach, brought about through the instrumentality of the medicament under deliberation.

The most striking of all the issues proceeding from a sufficient dose of veratrum viride is, of course, the profuse skin transpiration because it is visible upon the surface. This, as made manifest in some of the case reports preceding, lowers the temperature of the body, where it is elevated above the normal, in one instance effecting a reduction of five degrees Fahrenheit, and that within a short time. It always acts promptly in lowering temperature, when above the normal, through the cooling that happens from evaporation over the whole body surface. The removal of waste and pernicious elements which this immense transudation involves may, by checking metabolism, so tranquilize the heat-centers as to arrest heat-production; or, the cooling which follows the pouring out of the surface flood may be competent to quiet the irritability of the heat centers. Or, yet again, after such an overflow and withdrawal of the fluids of the body, in the general acceptation of the neuron-theory, there must be some retraction of nervous processes from a lack of distending fluid to maintain them in contiguity. This should cut off the centers from further control in heat-production. But it has a yet wider interpretation, which is borne out by the clinical fact that there is a state of somnolence under full doses of veratrum viride that, by a retraction of the nervous processes, reflexes are cut off and there is no passage over of irritations from center to periphery, or from periphery to center. It is not altogether improbable that this explains the behavior of veratrum viride toward the nervous system better than the bare statements that it is "a depressant to the spinal cord" or "acts upon the motor side of the cord."

The theory just enunciated may be dubbed the mechanical theory of action, but it receives confirmation by the conduct of the heart under veratrum viride. From rapid, inordinate effort this muscular engine is slowed and quieted. This does not come about through an inhibitory power conveyed by the pneumogastric, but by the action of the drug upon the heart-muscle itself or its ganglia. It induces in the heart-muscle, as in the nervous tissues, a retraction or contraction —for heart-muscle does not retract much—which is a conservative process in that it squeezes out from the fibrils all waste and noxious products, brings the organ down from a distended overacting mechanism to one working in perfect order and to the best advantage. In this way it protects the heart-muscle from the pathological changes that so often accompany toxemias.

It is also worthy of note that a reduction of the body-heat to the normal, or approximately so, retards greatly the activity and multiplication of pathogenic organisms. Conversely, phagocytosis continues energetically, the destruction of harmful microbes goes on unhindered—a process of great consequence in overcoming toxemia.

There remains another toxemia in which veratrum viride may prove a most excellent remedy. This is acute alcoholism. I have had no experience in its use, but, from employment of its congener, pilocarpine, in this class of cases, there is no doubt that, from the similarity of its action, veratrum viride should be equally efficacious. I was among the first to show the value of pilocarpine in alcoholism in the Medical News of September 19, 1885. It has the advantage over veratrum viride in not producing retching and vomiting, if, indeed, this should not prove to be a disadvantage therapeutically. H. C. Wood, Jr.,[1] states that he has knowledge of a death produced by veratrum viride in delirium tremens and, therefore, he condemns it in this condition. As, however, in the consideration of its toxicology, he declares that the drug is perfectly safe in any single dose in which it may chance to be administered, it is fair to presume that in the instance he refers to the man may have died in spite of it. Occasionally a patient with delirium tremens inconsiderately dies. If deaths from delirium tremens are chargeable to the medicaments ingested there are not many articles in the materia medica that should be considered safe to use in the treatment of this trouble.

In regard to the preparation employed, use has always been made of Norwood's tincture, boiled and filtered. In reference to the method of administration, the hypodermatic is preferred in all cases when prompt action is desired. Sometimes there is considerable soreness and induration from the injections which may persist for a week or two, but abscesses have never been observed.

Plague at Cape Town.—This continues to be serious. New cases are reported daily. A general epidemic is not feared, however.

[1] *Op. cit.*, p. 160-1.

THE TREATMENT OF DELIRIUM TREMENS BY THE INTRAVENOUS INFUSION OF SALINE SOLUTION.[1]

By JAMES P. WARBASSE, M.D.,
OF NEW YORK.

The disease under consideration is characterized by auto-intoxication. A chronic degeneration of the glandular structures of the body results from the prolonged use of alcohol. Particularly when the whole organism suffers the shock of traumatic injury, the secreting and excreting structures, by virtue of these degenerative processes, become disturbed in their functional equilibrium and a toxemia results. The identity of the peculiar toxins of delirium tremens has not been determined. It must be assumed, however, that these toxins are in part waste materials which are dependent upon the emunctory organs for their elimination and in part the so-called internal secretions of organs, which in the normally-balanced organism play a physiological rôle. Delirium tremens is characterized by the action upon the nervous system of these products, which, by virtue of the pathological conditions present, fail to become eliminated, absorbed or neutralized.

In the majority of these cases the natural resources of the system are sufficient to overcome the toxemia, and the glandular equilibrium becomes restored. In a certain class of cases the intoxication is fatal, even in the presence of kidneys which are able to excrete an adequate amount of urea.

The great value of intravenous salt infusion in cases in which the blood contains a profoundly poisonous amount of toxic substance has lead the author to apply this method of diluting and hastening the elimination of the poison in the extreme intoxication of delirium tremens. This opportunity is taken to place on record the following experience, occurring in the service of Dr. Pilcher in the Methodist Episcopal Hospital in Brooklyn. The patient was a man, thirty years of age, an habitual drinker of whisky. The urine showed the evidences of but a very moderate degree of urea-eliminating derangement. He suffered a fall from a wagon, sustaining a contusion of the side of the chest and abdomen and a slight wound of the scalp, with transient cerebral contusion symptoms. He regained full consciousness in about an hour. The first symptoms of tremor appeared a few hours after the injury. This continued in a slight degree until the third day, when the temperature rapidly rose to 104.2° F., and the patient became profoundly overwhelmed with the disturbances associated with a violent attack of delirium tremens. The pulse became rapid and weak, and on the fourth day the temperature was 105° F. Until this time sedatives and the routine treatment for delirium tremens had been employed, together with alcohol-sponging for the fever. On the fifth day his general condition was still worse. The heart was weak and rapid. The skin was cyanotic and bathed in cold perspiration. The delirium was of the low muttering type, and the general picture was that of a case profoundly overwhelmed with some virulent systemic poison, which promised to terminate fatally within thirty-six hours. At this stage an infusion of 1,200 c.c. (40 ounces) of saline solution at a temperature of 116° F. was introduced into the median cephalic vein. The change that came over the patient was a most striking one. The circulation rapidly improved, the delirium subsided, and the patient regained consciousness, all within a few hours. On the day following the temperature had subsided to 99.6° F., and the complete recovery was rapid and uneventful. The changes in this case were so rapid and striking that it seemed like a resuscitation.

The infusion in such cases as this accomplishes the following things: It increases the amount of the circulating medium in which the toxic materials are dissolved, thereby diluting the poison and bathing the nerve-centers with a more attenuated solution of the same. The amount of circulating fluid is increased above the normal, so that the excretion of fluids through all the fluid-excreting channels is increased, thereby carrying off in solution much of the contained toxins. The action of the heart is improved by the filling of the relaxed vessels. These suffice to restore the physiological equilibrium and turn the balance in the favor of recovery. Thus we may add indefinitely to the uses of this most valuable therapeutic measure.

YOHIMBIN AND ITS SALTS; A NEW APHRODISIAC.

By ROBERTS BARTHOLOW, M.D., LL.D.,
OF PHILADELPHIA;
EMERITUS PROFESSOR OF MATERIA MEDICA, GENERAL THERAPEUTICS AND HYGIENE IN THE JEFFERSON MEDICAL COLLEGE.

The remedies composing the group of aphrodisiacs have usually been disappointing. Some of them stimulate the function in a spasmodic way and have no power of sustained action; others irritate the genito-urinary tract and set up structural changes in the kidneys, and others induce profound nutritive disturbances, like acute yellow atrophy of the liver. Cantharides is a representative of the former group, and phosphorus of the latter. There is, therefore, a distinct need of a remedy, which shall be active in effecting results, but free from after complications.

In the issue of the *Therapeutische Monatshefte* for November, 1900, there is an account of yohimbe, a new aphrodisiac, which seemed competent to supply the existing deficiency. The chemistry, physiological action and therapeutical properties of the new remedy have recently been investigated at Berlin. One capable and enterprising pharmacist, Mr. Frank E. Morgan, has procured a supply of the new remedy, and I have repeated much of the experimental work with the view to ascertain whether the remedy has preserved its powers after transportation across the Atlantic. Before giving an account of my own researches, I submit an abstract of the work of our German colleagues.

Historical.—Specimens of the plant were sent to Berlin from a German colony established in equatorial Africa. It was ascertained to be a member of the *Apocynaccae*, and the native name is yohimbe, or yumbehoa. The bark is the chief source of the active principle. The chemical investigation was made by L. Spiegel who separated an alkaloid which he named yohimbin. It is a crystallizable principle and has the formula $C_{23}H_{49}N_2O_4$. It combines with acids to form salts, as the sulphate, nitrate, phosphate, etc.[1] The most useful salt for internal administration is the chlorhydrate. The physiological investigation was made by Oberworth[2] with the following result:

The toxic dose of yohimbin for rabbits is 0.011 gram given intravenously and 0.053 gram subcutaneously, per kilogram of body-weight.

In frogs yohimbin causes a complete paralysis of the nervous system, with periods of slight remission of effect, proportional to the size of the dose and the duration of the action. The same effects occur in warm-blooded animals.

In cold-blooded animals (frogs) yohimbin inhibits the heart's action, finally stopping it in diastole. The previous administration of atropine does not prevent this result. It, also, paralyzes respiration, and if artificial respiration is resorted to death ensues by failure of the heart. The blood-pressure is lowered as soon as the injection is practised, and the pulse sinks proportionately. The blood-pressure falls, not alone through collapse of the arterial wall, but from weakness of the heart itself, and when a temporary rise of the pressure is caused by compression of the abdominal aorta it has no influence on the result. The heart's pulsations are not increased by section of the vagi, or by the injection of atropine, nor does irritation of the vagus center affect the pulse-rate, and peripheral stimulation of the vagus is equally without influence. The effect of yohimbin on the heart must be due, therefore, to an action on the sympathetic or on the motor ganglia of the heart, or on both.

Yohimbin acts on the genital apparatus in a marked manner, in warm-blooded animals. In various animals erections and emissions occur in a notable degree. The smaller doses cause unrest, excitement, erections of the genital apparatus. Large doses cause violent spasms, followed by prolonged weakness. No ill effects have followed in the sexual organs, and the kidneys remain unhurt by the considerable hyperemia which occurs throughout the genito-urinary system.

Therapeutic.—Clinical studies of yohimbin and its salts were made by Löwy, Mendel and others. Löwy observed marked aphrodisiac effects, swelling of the testes, and erections of the penis, but even if these effects were long continued they were not followed by any permanent injury to the sexual apparatus, unlike in this respect to the action of cantharides. It was noted especially that yohimbin does not cause any structural alterations of the kidneys. The observations of Löwy have been supplemented and confirmed by Mendel. In cases of sexual neurasthenia he found yohimbin most useful. However, in tabes and in other organic spinal affections it appeared to have no curative action.

My course of investigation included some simple observations on the effects of yohimbin (the chlorhydrate) on cold and warm-blooded animals. It is not actively toxic. The lethal dose for a medium-sized frog is $^1/_{10}$ grain, for an ordinary gray rabbit, $^1/_4$ grain. In observations on adults I found that the dose should be from $^1/_{20}$ grain to $^1/_5$ grain. Mendel advises a one-per-cent. solution of the hydrochlorate, of which he administers five to ten drops, making the dose $^1/_{20}$ to $^1/_{10}$ grain. It is not soluble in such proportion without the aid of heat.

When a frog is injected subcutaneously with $^1/_{10}$ grain, in a few minutes some irregularity of muscular movements is observed, paresis comes on, and nearly rhythmical muscular contractions take place at intervals. When the limbs are extended, they remain so for a few seconds, and are then drawn up in the usual position. When the toes are smartly pinched they are freed by a succession of rapid movements. Complete paralysis at length ensues, the animal lies extended, but occasional muscular spasms occur from above downward. Up to complete loss of muscular power, movements ensue on pinching the toes. Electrical, mechanical, and chemical irritation cause muscular movement and irritation of the sciatic nerve, separated, also induce contractions of the leg muscles, showing that the paralyzing action is central, not peripheral.

The action of the heart ceases in diastole and both cavities are distended. Electrical stimulation causes no response. Section of the pneumogastrics and section of the cord high up are alike without influence on the mode of termination of the heart's movements, so that we may conclude with our German confrères that yohimbin acts on the cardiac motor ganglia.

There is close resemblance in the action on cold- and warm-blooded animals (rabbits). Paresis with trembling, followed by paralysis of motility, ensues on injection of yohimbin ($^1/_4$ grain). There is fibrillary trembling of the muscular system followed by spasmodic contractions, and nodding movements of the head. Sensibility is not impaired, but rather heightened, and muscular contractions on mechanical, chemical and electrical stimulation always take place until the centers are overpowered. It is a central and not a peripheral paralyzer.

The respiratory movements are affected by a succession of spasmodic shocks of the muscles of respiration until they finally cease. This effect is exerted on the centers in the medulla and is not changed by division of the pneumogastric. The action of the heart becomes more or less irregular, with the progress of the systemic impression, and ceases finally in the diastole.

[1] Chemiker-Zeitung, as quoted in Therap. Monatshefte, November, 1900.

[2] Virchow's Archiv, Band 153.

Changes in the tension of the vascular system, division of the pneumogastric, do not change the action on the heart's movements.

Male rabbits are notoriously possessed of an active state of the sexual function. Under the influence of yohimbin this natural state is much intensified. A condition of hyperemia of the genito-urinary tract is set up, including the kidneys and bladder, especially about the prepuce.

To illustrate the mode of action of yohimbin in general on warm-blooded animals, I give the details of the effects of a less than lethal dose of the alkaloid: A medium-sized gray rabbit received by hypodermatic injection one-fourth of a grain. In an hour there occurred some weakness and irregularities of gait, some spasms of the muscles of the legs, and of the neck, followed by general muscular weakness, and inability to stand. He fell on his side and was unable to rise, but when his toes were pinched, he made efforts to move them away. His respiration was irregular and interrupted by what seemed to be spasms of the diaphragm. The action of the heart was irregular; the pulsations in general were frequent and weak, but occasionally a stronger one would occur. Then came on the nodding movements of the head which were nearly rhythmical, but often interrupted by more active convulsion extending from above downward. The kidneys acted copiously and the bowels moved freely. At the end of two hours the rabbit lay on his side, motility lost, and only faint breathing movements could be detected. In another hour he began to make feeble movements and attempts to rise when his toes were pinched, the respiratory and cardiac movements increased in regularity and volume, and at the expiration of another hour he began to nibble at a carrot placed near him, and finally got on his legs, which at first were feeble. The next morning he was quite lively, seemed nowise injured by his experience, ate freely of carrots, and drank water.

The experiments made on animals indicate that yohimbin is a central paralyzer of motility, but not of sensibility. With the muscular paresis occur spasms of the muscles and nodding movements of the head involving the neck muscles. It affects respiration by acting on the chest muscles and the diaphragm. The heart's action is weakened by it, and ultimately the organ is paralyzed, stopping in the diastole. This result is due not to peripheral impressions, but to an action of the cardiac motor ganglia. It is not a muscular poison; the muscles themselves and the motor nerves react to mechanical and electrical excitation.

The most interesting point regarding yohimbin is its effect on the sexual system. That it causes hyperemia of the genitals and increased activity of the apparatus seems undoubted. That it increases the sexual function is apparent, but it does not appear to set up any inflammatory action in the kidneys.

Clinical.—Sufficient clinical experience has not yet accumulated to permit an authoritative judgment of its therapeutical value. Mendel of Berlin found it useful in sexual neurasthenia, but thus far my own results are rather negative in this respect. It may be the dose used has not been sufficient to develop this action in man. The dose favored by the Berlin observers, as already stated, ranges from $^1/_{20}$ to $^1/_{10}$ grain. In prescribing it for adults I have not gone beyond $^1/_{20}$ grain. This has not proved sufficient to excite the sexual organs in healthy adults.

That it should prove useful in sexual neurasthenia, in depression of the sexual organs by age and premature debility, seems warranted by the mode of action disclosed in the experiments on animals.

My own interest in the remedy has been rather the expectation that we should find yohimbin useful in albuminuria. The fact that it has a marked effect on the renal and genito-urinary systems indicates that it may exert an action of substitution in diseases of these organs. But to what extent it may have a curative effect in renal diseases can only be determined by a more extended clinical experience.

THYMOTAL; A NEW REMEDY FOR ANKYLOSTOMIASIS.

By J. E. POOL, Ph.G.,
OF PARAMARIBO, DUTCH GUIANA.

When my little daughter was suffering from ankylostomiasis, I saw the terrible effect of thymol and how difficult it was to take; I saw the little boy of my cook drop dead shortly after he had taken thymol pills; I saw a baby suffocated by thymol electuarium and learned that two patients at the Military Hospital had become blind by the use of large doses of extractum filicis, usually prescribed for ankylostomiasis. I then determined not to rest until I had found a less dangerous and better remedy for this dangerous and very frequently-occurring malady of the tropics.

After much difficulty I succeeded in making a carbonate of thymol as has been done of guaiacol, and I called it "thymotal Pool." Its preparation takes place by the influence of phosgen gas on thymolnatrium, leaving after purification an insipid, white crystalline substance, the smell of which only feebly reminds one of thymol.

It is a neutral substance, with a fusing-point of 49° C. and a boiling-point of more than 400° C., and it gives no other reaction save of its having been divided into thymol and carbonic acid by an alcoholic solution of potassa. The influence of an alcoholic potash solution resembles that of an alkali in *status nascendi* like the saponifying action of the intestines. A boiling aqueous solution of potash does not break it up and neither acids nor the human stomach have any effect on it.

Seven patients were treated for ankylostomiasis with the new remedy in the Military

Hospital with excellent results, as is evidenced by the following report of the medical officers of the hospital:

Drs. E. A. Koch, J. W. van Rijn and C. van der Meer, medical officers at the Military Hospital of Paramaribo, declare herewith that seven patients, children as well as adults, have been treated with favorable results in this Hospital with the new remedy, thymotal, and that this new remedy is far to be preferred to thymol, for the following reasons:

(1) Because it is without odor and can therefore be taken by children who cannot swallow pills. At the same time the danger of being suffocated by thymol electuarium, which occasionally happens in infants, is avoided; (2) because it is not dissolved in the stomach, as is thymol, and is not vomited, as is often the case with this drug; (3) because thymotal does not cause giddiness, as thymol does very shortly after it is taken; (4) because the danger of thymol-poisoning is reduced, especially in those children whose bodies are weakened by *Ankylostoma*; (5) because the carbonate of thymol is broken up in the body by the influence of the bile and the mucus of the intestines and thymol is formed exactly at the places where the *Ankylostoma* are found in the body, *i. e.*, the duodenum and the adjacent parts of the intestines ;(6) because it cures more rapidly than does thymol (as far as can be judged from the treatment of so small a number of patients).

As is universally known, the malady ankylostomiasis is known in all tropical countries, for instance, in West India (in the Antilles the malady is called "malcœur"); in Colombia, where it is called "tuntun"; in the Brazils, where it is called "opilaças"; in Egypt, where it causes the so-called "Egyptian chlorose"; in Italy; in Switzerland, where it causes the "Minen" or "Grubenkrankheit." In the Dutch East Indies the malady seems to be known in some regions, but it appears that no efficient remedy is known there. In other regions it seems to be unknown and it has even happened that medical officers from the East Indies, who had been sent to Surinam, did not know the malady. On the other hand, several Javanese, among the immigrants freshly disembarked, suffered very much from the disease. At Delhi, where the workmen find very praiseworthy medical attendance, the disease is a true curse, as it also is at Surinam.

In this Colony, with a population of about 40,000, nearly 60 kilos (120 pounds) of thymol are consumed yearly, which proves that the population receives very good gratuitous medical attendance, but I feel sure that in other countries the disease will be equally prevalent.

In Europe experiments with the new remedy were made by Mr. Stheeman on round worm and tapeworm. These experiments are still going on, but it has been stated that the remedy is very efficacious, consequently it will soon compete with male fern, pomegranate, santonine and cooso.

The directions for this remedy are as follows: For adults, grams 2.0 (30 grains); for children, gram 1.0 (15 grains), and for babes, gram 0.5 (7.5 grains) three or four times daily. This treatment must be continued for four days and a purgative must be taken on the fifth day, after which the whole treatment must be repeated until no more eggs of *Ankylostoma* are found in the stools.

BELLADONNA VS. SCOPOLIA.[1]

By REYNOLD WEBB WILCOX, M.D., LL.D.,

OF NEW YORK;

PROFESSOR OF MEDICINE AND THERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN TO ST. MARK'S HOSPITAL

So much has been presented in regard to this question and so many discordant statements are to be found in literature that it has been deemed important that the facts in regard to the relative value of belladonna and scopolia should be investigated and an unbiased opinion reached.

The status of the belladonna-scopolia question is as follows: The present belladonna plaster of the Pharmacopœia is but little used, owing to objections both to the leaf extract, from which it is made, and to the mass used as a basis. Plaster manufacturers, therefore, resort to the root extract instead. This root extract is prepared, for the most part, both in this country and abroad, from the scopolia rhizome (*Scopolia carniolica*), more or less of the scopolia root also intermixed, instead of from belladonna. It is claimed upon one hand that this rhizome and root yield a separate article from a therapeutic standpoint, and that is is used because of cheapness. Incidentally, it has been claimed that the scopolia plaster is nearly inert, and again, that it is extremely dangerous—the latter claim being based upon its content of hyoscine. Upon the other side, it is claimed that it does not differ in kind of action from the belladonna-root plaster, the percentage of hyoscine being extremely small and the hyoscyamine present acting the same as atropine. It is also claimed that if the present extensive use of scopolia were to be turned over in favor of belladonna root, the supply of the latter would become insufficient to meet the demand.

This controversy has been carried on up to the present time very largely in commercial circles, yet the suggestion has been urged upon the Pharmacopœia Revision Committee that it authorize the use of scopolia extract in plaster-making, either independently, or as an alternative for belladonna, at the option of the manufacturer. Under these circumstances the Research Committee of the American Pharmaceutical Association, one of the chief duties of which is to work in the interest of the Pharmacopœia, concluded that it was desirable for it to undertake this investigation, and Dr. H. H. Rusby, Professor of Botany and Materia Medica at the New York College of Pharmacy, assumed

[1] Read before the Medical Society of the State of New York at its ninety-fifth annual meeting, held at Albany, January 29, 1901.

the duty of bringing it about. The steps which were taken were as follows:

Three lots, each of twenty-five pounds, of belladonna root were secured in the New York market, each lot representing a different importation. This root was all examined by Dr. Rusby, piece by piece, to be sure that it contained no foreign matter of any kind. It was then mixed and prepared for powdering. Similar action was taken in the case of three lots, each of twenty-five pounds, of scopolia. All the root pieces of the latter, because of their close resemblance to belladonna root, and because some of them might possibly have represented an admixture, were thrown out. These represented about 5 per cent. or more of the entire amount. These two articles, that is, the belladonna root and the scopolia rhizome, were sent to a large manufacturer of the highest reputation for the excellence of his manufactured drugs, but not interested in this discussion, with careful explanation of the nature and importance of the work, and a request was made that they be made up into fluid extract, tincture and total alkaloids, with the greatest care possible. This was done under the direction of an expert, who resorted to processes which were certain not to effect any change in the original nature of the alkaloids contained, evaporation by the cold process being strictly adhered to. One-half of the total amount of each drug was converted into fluid extract, tincture and extract, while the other half was used for the complete extraction of the total alkaloid. Of this total alkaloid one-half was retained for the purpose of being examined chemically, microscopically and optically. Of the remaining half a portion was used in making a large number of one-five-hundredths-grain tablets, and the remainder employed for experimental purposes. All this alkaloid, it must be stated, was first converted into the form of the hydrochloride. The alkaloids have been experimented with by others and will be the basis of separate reports.

Coming now to the galenical preparations, it was found that the scopolia rhizome assayed 0.55 of 1 per cent. total alkaloids—a rather low yield as compared with other assays. Its fluid-extract assayed the same, and it was from this that one of the liniments was prepared. The belladonna root yielded the extremely high percentage of 0.93, and its fluid-extract, of which the other liniment was made, yielded the same. The extract showed also a great difference, the belladonna containing 2 per cent. of total alkaloids and scopolia 1.6 per cent.

Not having any interest in plasters, I chose the liniments (95 parts of fluid-extract with 5 parts of camphor) for my experimental work. I received from Dr. Rusby two bottles marked only "A" and "B," but without any clue as to their contents other than that each contained a liniment derived from one or the other of these sources. The method pursued was as follows: A quantity of the liniment (noted in each experiment) was taken and, after the temperature, pulse, respiration and general condition of the adult had been recorded, this was rubbed into the inner surface of the forearm until the skin became again dry. Records were made at intervals of thirty minutes unless otherwise specified, the first being made immediately before using.

LINIMENT "A."

No.	Amount.	T.	P.	R.	Pupils.	Mucosæ.	Skin.	Tongue.
1.	20 drops	99.4	88	22	Medium	Pale	Cool	Moist
		99.6	89	26	Medium	Pale	Cool	Moist
		99.5	88	28	Medium	Pale	Warm	Moist
2.	20 drops	99.4	88	18	Contracted	Pale	Warm, dry	Moist
		99.8	90	28	Dilated	Pale	Warm, dry	Moist
		99.9	100	28	Dilated	Pale	Warm, dry	Moist
3.	20 drops	99.2	88	20	Medium	Red	Warm, dry	Moist
		98.4	80	20	Medium	Red	Warm, dry	Moist
		98	84	18	Medium	Red	Warm, dry	Moist
4.	20 drops	98	80	18	Contracted	Pale	Warm	Moist
		98	80	20	Contracted	Pale	Warm	Moist
		98	80	20	Contracted	Pale	Warm	Moist
5.	20 drops	98.4	78	24	Medium	Red	Warm, dry	Moist
		98.4	78	24	Medium	Red	Warm, dry	Moist
		98.4	78	24	Medium	Red	Warm, dry	Moist
6.	20 drops	100.2	96	24	Contracted	Red	Moist	Moist
		99.2	88	26	Contracted	Red	Moist	Moist
		100.2	100	24	Contracted	Red	Moist	Moist
7.	40 drops	98.4	110	22	Contracted	Pale	Warm, dry	Moist
		97.8	100	18	Contracted	Pale	Warm, dry	Moist
		99	120	20	Contracted	Pink	Flushed	Dry
8.	40 drops	98.6	74	20				
		98.6	84	28	Pupils slightly dilated, headache, thirsty and nauseated.			
9.	50 drops	98.2	74	20				
		98.6	80	30	Headache, nauseated, very sleepy.			
10.	60 drops	98..	50	20				
		98.4	60	28	Flushed face, nauseated, slight headache, thirsty and pupils slightly dilated. Sleeping.			
11.	60 drops	98.2	70	18				
		98.4	80	30	Nauseated, severe pain over heart, face flushed, pupils considerably dilated, extremely thirsty and very drowsy.			
12.	60 drops	98.6	120	20	Medium	Red	Cool	Moist
		98.6	120	22	Medium	Red	Cool	Moist
		100.2	130	24	Slightly dilated	Red	Flushed	Dry
		101.2	133	26	Dilated	Red	Flushed dry	Dry
					(The last record was made two hours after using the liniment.)			
13.	70 drops	98.2	100	24				
		98.6	80	30	Peculiar feeling in chest; moderate dyspnea, nauseated; flushed face; headache; intense coughing lasting five minutes; dilated pupils; extremely drowsy.			
14.	70 drops	98.2	70	18				
		98.4	80	30	Very drowsy and slightly nauseated. Relief of pain in back at point of application. Very drowsy, dilated pupils. (This application was made over the site of a lumbago).			
15.	70 drops	98.4	70	24				
		98.6	84	30	Pain in head; numbness of arms; slightly nauseated; flushed face; thirsty and very sleepy.			
16.	80 drops	98.2	74	28	(Liniment applied to axilla.)			
		98.4	80	30	Face slightly flushed; difficult respiration; drowsy; thirsty; one pupil slightly dilated.			
17.	80 drops	98.2	98	20				
		98.4	100	30	Headache; nausea; pupils slightly dilated; thirsty. (This is the same patient as No. 16, but four days later.)			
18.	80 drops	98.2	98	18				
		98.2	106	26	Slight headache.			
19.	90 drops	98.6	56	20				
		99.2	68	30	Headache; nauseated. (The same patient as No. 18, but six days later; under the influence of digitalis.)			
20.	90 drops	97.2	90	24				
		98.2	96	30	Nauseated; headache; pupils slightly dilated.			

From these observations, considering the rise of temperature, pulse and respiratory rate, difficult respiration, the flushing of the face, reddened mucosæ, dry tongue and thirst, headache, drowsiness and dilatation of pupils—these symptoms becoming more marked as the amount of the liniment was increased—there was no doubt but that liniment "A" is very active and contains an atropinaceous alkaloid. In No. 12 poisonous symptoms were well marked.

LINIMENT "B."

No.	Amount.	T.	P.	R.	Pupils.	Mucosæ.	Skin.	Tongue.
1.	30 drops	100.2	110	24	Medium	Pale	Hot, dry	Dry
	= 17 drops of "A"	100	110	24	Slightly dilated	Pale	Hot, dry	Dry

In all of these experiments there was no change in the color or dryness of the mucosæ or in the tongue; there was no flushing of the skin nor any nervous symptoms. The only conclusion which can be reached is that, excepting for the very moderate and inconstant changes in temperature, pulse and respiration, liniment "B" is inert.

After completing my observations I reported to Dr. Rusby that I had reached the opinion that the effects of liniment "A" were those of an exceedingly active preparation of belladonna. He then informed me that my opinion was correct and called my attention to the following:

"You have, therefore, to consider that your 'A' liniment made from the belladonna fluid-extract compared as .93 to .55 with your 'B' liniment made from scopolia fluid-extract. In estimating your comparative results, therefore, you must make allowance for this difference in strength."

Even after making due allowance for the difference in alkaloidal strength, the opinion still obtains that, as far as its use as liniment is concerned, scopolia is unproductive of results. For comparison in tabulating my results I have placed the equivalent alkaloidal strength of "B" in terms of "A."

Whether the alkaloids of scopolia (mostly hyoscyamine, with small quantities of hyoscine) are, on account of their nature, not absorbed when exhibited as a liniment, but would be if applied in a plaster form, this investigation does not, of course, determine, but others now working upon that question will soon be in a position to report. My work has established but one fact: Scopolia rhizome as fluid-extract incorporated into a liniment is devoid of therapeutic action and should not be substituted for belladonna root.

Experiments made with plasters and ointments from belladonna root and scopolia rhizome are not yet completed, but thus far very little difference in their activity has been developed. In order to determine if the camphor in the liniment interferes with the production of symptoms from the use of scopolia liniment, a new series of observations has been commenced which will be the basis of a later report.

To Drs. H. D. Furniss of the Post-Graduate and H. J. Van Wagenen of the St. Mark's Hospital house staff I would acknowledge my indebtedness for efficient assistance in prosecuting this investigation.

749 Madison Avenue.

IMMUNIZATION FOR TYPHOID FEVER: A REVIEW.

By H. W. McLAUTHLIN, M.D.,
OF DENVER, COLORADO.

The efforts made during the past few years to produce artificial immunity from typhoid fever must be considered as especially far reaching in importance. In 1892 the experiments of Brieger, Kitasato and Wasserman on animals were reported. They grew typhoid bacilli in thymus bouillon for three days. They claimed that an antitoxic body in the thymus cells reduced the virulence of the typhoid poison so that after heating the thymus culture to 60° C. for fifteen minutes it became sufficiently attenuated to be safe to use in man and at the

same time sufficiently protective. They injected six mice with 0.5 c.c. of this specially-prepared thymus bouillon. The animals thus treated did not show any signs of illness. After twelve days the six protected and three control mice were inoculated in the peritoneal cavity with 0.3 c.c. of the most virulent typhoid bouillon. The three control animals died in fourteen hours. The protected animals all survived without signs of sickness.

Passing the work of the other investigators in this line, special interest centers in the work of Dr. A. E. Wright and others, of the English army, teachers in the army medical school at Netley, particularly because of the favorable opportunity of these men to test the value of the inoculations on British soldiers in India and South Africa.

In the *British Medical Journal* of January 30, 1897, and also in the *Lancet*, the first extended paper of Dr. Wright on this subject appeared. In it he said that the vaccination experiments against cholera by Haffkine prompted him and his associates to take up the question of establishing artificial immunity from typhoid. His first published vaccinations were made in July and August, 1896. Regarding the principles of the proposed method, he said that all vaccination has for its object, first, to achieve a degree of immunity equal to or greater than that which comes from an actual attack of the disease, and second, to obtain this immunity without risk to life or health. The first can be obtained as yet only by inoculation with the micro-organisms of the particular disease or their products. The second can be accomplished in a number of ways; as, for example, in vaccination against smallpox, by inoculating with micro-organisms which have lost their virulence for man by passing through certain animals; or, as in Pasteur's vaccination against anthrax, in which use is made of artificially-attenuated micro-organisms; or, thirdly, by using measured quantities of dead, but still poisonous micro-organisms. The latter method was adopted by Professor Wright.

His vaccine consisted of a pure cultivation of typhoid bacilli in broth or agar-agar. When time was allowed for the material to be obtained from Netley, it consisted of lysolized cultures (1 per cent. lysol), four weeks old, of virulent typhoid bacilli. This pure cultivation, with its contained toxins, is sterilized by subjecting it to a temperature of 60° C., thus destroying the typhoid bacilli, or possibly in some cases so lowering their vitality that they cannot produce fresh poison, or can produce it only in such quantities and of such a character that it cannot prove fatal when introduced into the tissues of man.

The vaccine is thus not a serum nor a lymph. Living animals are not at any stage required to produce it and the only use made of animals is to test the strength of the fluid to insure the proper standard.

In general characteristics the vaccine corresponds closely to that used by Haffkine in his cholera inoculations. The strength of the vaccine varies with the number and the virulence of the bacilli it contains; so the dose has varied, but seems to have been between 0.3 and 1 c.c. The latter makes a full dose for a man, and represents an amount which would prove fatal to a 350-gram guinea-pig.

Dr. Wright gives the following symptoms as occurring after a person has been inoculated: From a small dose there is locally slight tenderness at the site of the injection (generally the flank). There is a feeling of chilliness two or three hours after the inoculation, with a slight rise of temperature and some restlessness at night. In twenty-four hours the symptoms are gone. From larger doses the local tenderness increases and extends upward to the armpit and downward to the groin. A reddened patch, two to four inches in diameter, appears at the place of injection and red lines of inflammation extend from this up to the armpit. The local symptoms are at their height in twelve hours, still very sensible at twenty-four hours, and are gone in about forty-eight hours. Constitutionally there are usually feelings of faintness or collapse within two or three hours after the injection. Sometimes there is vomiting. The appetite is lost. There is considerable fever and sleep is much disturbed. Within a day or two the symptoms are gone and the patient feels normal. Occasionally a patient looks poorly for two or three weeks. Considerable edema may occur at the site of injection, and in one case it extended to the linea alba in front and downward to the groin. Wright thinks he largely prevents this by administering calcium chloride.

The *British Medical Journal*, January 20, 1900, says editorially: "The patient (after inoculation) passes through what may be called a modified attack of typhoid fever, an attack modified both in degree and in kind. If the bacilli are killed, the reaction, however smart it may be, is usually temporary; if the bacilli are not dead the process is more prolonged and it is probable that the protection is also greater and more prolonged. It is possible that as the process becomes better understood and the necessity for a greater degree of protection becomes evident, the living but modified virus may be more generally used."

Through the courtesy of Dr. Smith, of Littleton, I can add the testimony of a physician who himself took the inoculation, Dr. Charles Peters of the Imperial Yeomanry. In a recent letter he says: "You know there is an antityphoid inoculation on trial now, and this war (South African) will prove it to be good or not, as many of the troops have been inoculated. I had it done. I thought it would be worth trying. They injected 1 c.c. into the muscles just above the anterior superior spine of the ileum. In four hours it commenced to work. At first it makes one feel very faint, then causes perspiration and

high temperature (102°-104° F.) with a frightful headache. Some it makes vomit, so, of course, I had my share of that. This lasts twenty-four to thirty-six hours and, in the meanwhile, the whole of the side becomes very sore. It sets up an acute cellulitis at the site of the injection and a lymphangitis extending to the axilla and groin, where an adenitis is developed. In my case it did not spread to the groin. Then one gets well very quickly and the side is quite normal in three or four days. I can assure you it is not pleasant at the time, but, if it lessens typhoid or prevents it, it is worth the day or two of illness, at least so I think now; but if I had to take it again I might think otherwise."

The blood of patients who have submitted to the typhoid vaccination becomes poisonous in some measure to the typhoid bacillus, as it immobilizes and agglutinates them, *i. e.*, it responds to Widal's test. Wright considers that this agglutination power of the blood is a trustworthy criterion of the immunity of the person who furnishes it. He admits, however, that before this can be called proven, the fact must be explained that persons who die from typhoid show the specific agglutination reaction in exactly the same way as patients who recover from this disease. He believes that it may be assumed that every animal is working its way up to the acquirement of immunity from the moment of infection up to the time its struggle with the disease finally ceases. A degree of immunity which would amply ward off a fatal issue if given on the first day of the disease may be of no avail if acquired later in the attack. So in typhoid the aggultinating power of the blood may be acquired too late in the attack to save the patient's life. The agglutinating power of the blood acquired from an attack of typhoid is not greater than that acquired from an inoculation with dead typhoid bacilli.

The blood of an inoculated person is also tested to see how far it can be diluted and preserve its agglutination powers. The sedimentation units are then called preventive units. For example, a blood which shows the agglutination in a tenfold dilution is said to contain one preventive unit, and so on.

As to risk from inoculations, it is claimed that as the bacteria employed are dead, and so are thus incapable of generating new poison in the system, the injection of small and measured amounts of these dead bacterial cultivations would risk life no more than the injection of a medicinal dose of morphine. Haffkine has made nearly 100,000 anticholera inoculations without a serious symptom.

As to probable duration of immunity, with typhoid as with smallpox vaccination the immunity conferred probably diminishes more or less rapidly. Wright thinks that if, as seems probable, the duration of immunity will be told by a series of blood examinations, it would seem that immunity would last at least a few years and thus carry a young adult over the period of greatest susceptibility. Dr. Foulerton, in the *Middlesex Hospital Journal*, claims to have examined the blood of nine people two years after inoculation and in four out of nine cases it showed a definite agglutinative reaction. The *British Medical Journal*, January, 1900, says editorially: "Evidence has been established that the effect of inoculation is prolonged for eighteen to twenty-four months."

Sir Dyce Duckworth, lecturer of medicine at St. Bartholomew's Hospital, in an interesting report of two cases which he inoculated successfully with Wright's vaccine, says that a second inoculation, ten or twelve days after the first, is desirable to secure the full benefit of the vaccine.

In reviewing the literature on this subject, one finds the reports few in number and often incomplete, because no subsequent blood tests are given. For instance, we find that in 1896 eighteen medical officers, either in or preparing for service in India, were inoculated. Two hundred and fifty men volunteered at Bangalon in December, 1898. In March, 1899, there were 420 men inoculated at Lucknow, and so on. The following reports are from Wright. Of 200 attendants at the Maidstone Hospital, 95 were inoculated. During the subsequent epidemic of typhoid there none of these men were ill. Of the 105 who refused to be vaccinated, 19 contracted typhoid. At Khartoum six subalterns consented to be vaccinated. The remaining two refused and said they would take chances. One of the latter died and the other was very ill from typhoid. None of those inoculated took the disease.

A detailed account of the results of typhoid inoculations in the Indian British army, by Wright, appeared in the *Lancet* and also in the *British Medical Journal* in January, 1900. The statistics are as follows:

TYPHOID AMONG INOCULATED AND UNINOCULATED.

Period of observation	About 9 months
Total number of men under observation	11,295
Number inoculated	2,835
Number not inoculated	8,460
Number of cases of typhoid among inoculated	27 or 0.95 per cent.
Number of cases of typhoid among uninoculated	213 or 2.5 per cent.
Number of deaths from typhoid among inoculated	5 or 0.2 per cent.
Number of deaths from typhoid among uninoculated	23 or 0.34 per cent.

Of the inoculated cases who had typhoid, five were admitted to the hospital within 19 days after inoculation. Two of these died.

In connection with these figures, Wright calls attention to the conditions under which the inoculations were performed. They were made in the latter part of 1898 and early in 1899, while he was serving on the Indian Plague Commission. As the Commissioners journeyed from place to place, the soldiers were told of the supposed advantages of the inoculations, and volunteers were called for. The younger men and those newly arrived were especially advised to protect themselves, and these were the ones who usually took the inoculations. Those who considered themselves safe on account of age or a

previous attack were disposed to take chances. As sufficient vaccine could not be prepared before they left England, it had to be prepared *en route*. The bottles of vaccine had to be repeatedly opened in order to withdraw material when needed. Guinea-pigs, for standardizing the vaccine, had to be carried about from place to place, to keep them under observation. As an incubator could not be carried about with them, to prove the continued sterility of the vaccine, the latter was sterilized at 60° C. previous to making each new series of inoculations. Wright considers it possible that some of the vaccine was thus weakened by repeated sterilization. In no case was it possible to make two successive inoculations. The doses were always such as to produce fairly severe reaction in the men. The necessary statistics after the inoculation were difficult to obtain, owing to frequent changes in the stations of the men. In certain cases the inoculations were taken in the actual presence of a typhoid epidemic, and some of the men were undoubtedly incubating the disease at the time they were inoculated.

These statistics, moreover, do not include officers, as no accurate statistics were available in their case. Wright thinks, however, that several hundred inoculations have occurred among the subalterns alone. Among these only five cases of typhoid, all said to have been mild, have come to his knowledge. In closing this article on results he says: "Even assuming that no greater protection could be conferred in the future than that which appears to have been conferred in these preliminary inoculations, the result obtained would, in the aggregate, be a significant one. Taking the figures as they stand in the summary of the table, and calculating on the figures 1800 and 460, which represent in round numbers the average number of cases and deaths from enteric fever, in the British army in India, as deduced from the figures of the last three years, there would, on the assumption that the whole army, or the susceptible portion of it, were inoculated, be an annual saving of over 1000 cases of enteric fever and of nearly 200 lives."

Curiously enough, there have been numerous reports from India to the effect that the antityphoid inoculation also confers a certain amount of protection against malarial fever. Regarding this, Wright says that the only record he has bearing on it is that of one regiment. The question was asked each man if he had had malaria before or after the inoculation. Of 121 men who stated that they had had malaria before the inoculation, 111 were entirely free from it six months after, when the question was asked. The other 10 said that they had been practically free from it. Two men who had never had malaria previous to the inoculation said they had it slightly within the six months after. But this question is of secondary importance.

It is not surprising that the consensus of opinion seems to be that Wright's work has demonstrated the harmlessness of these inoculations, and also, which is Wright's modest claim, that some degree of protection against typhoid is conferred by them. It is quite possible that changes in the technic of the preparation of the protective material will be necessary. Wright himself admits that there have been uncertainties in the method of standardization which he proposes to deal with later. Fuller statistics are absolutely necessary and especially the following up of the inoculated cases.

Further to quote the *Lancet:* "Wright's results are not enthusiastic. A much larger number must be quoted. But these are sufficiently convincing to make officers willing to take the inoculations and to advise their men to do likewise. We agree with Wright that a certain measure of protection seems to have been conferred. Typhoid has hitherto been the greatest cause of death to British soldiers in peace or war. At the present time a most critical test is being made of the inoculation among troops in active service in South Africa." Also the *British Medical Journal:* "These figures are all in favor of the inoculations. Many of the attacks of typhoid in the inoculated seem to have been comparatively mild, although the fact that the general type of the disease at the time may have been mild must be remembered. The evidence thus far seems to show that the inoculations do exert a distinct effect on typhoid among the troops in India. Let the troops to be sent to South Africa be vaccinated during their period of training, before they go to the seat of war. Officers, nurses and members of the army medical corps, except those who have passed through an attack of typhoid, should be inoculated. Better still, if the treatment can be extended to the rank and file of both regulars and volunteers."

The latest report seen by the writer is a letter from the front, South Africa, and published in England, May 5, 1900. It states that it is still too early to know the results of the antityphoid inoculations in the present campaign.

Frank Billings, M.D., of Chicago, in the *Journal of the American Medical Association* February, 1900, says: "The production of artificial immunity from typhoid fever, as a prophylactic measure, by inoculation with typhoid cultures, has been practised with apparent success. The inoculations, however, are still too few and the results on man too indefinite to allow of positive deductions. Enough has been done to prove the harmlessness of the operation and to encourage a continuance of the practice. Many of the experiments have been weakened by the failure to apply the serum test before and at proper and repeated times after the inoculations."

Our American soldiers in the late military campaign suffered heavily from typhoid. Dr. Victor C. Vaughan, in his recent paper on "Conclusions Reached After a Study of Typhoid Fever Among the American Soldiers in 1898," says: "Every regiment in the United States

service in 1898 developed typhoid fever, and in all about one-fifth of all the soldiers in the national encampments. The deaths from typhoid were more than 80 per cent. of the total deaths. One who has lived in a camp in which typhoid fever is prevalent is liable to develop this disease any time within eight weeks after leaving such camp."

It is greatly to be hoped that the official reports of the results of the inoculations in South Africa may show another stride forward in the praiseworthy efforts to control this great scourge, not only of modern armies, but of young adult life everywhere.

MALARIAL FEVER, WITH SPECIAL REFERENCE TO THE VALUE OF BLOOD EXAMINATIONS; REPORT OF CASES.[1]

By HERBERT OLD, M.D.,
of Norfolk, Virginia.

It is the contention of the writer in this discussion to limit himself to the practical side of the question. I think all will agree with me that it is of the greatest importance to be able to be positive of the diagnosis of any disease which we are called upon to treat, and that the sooner the diagnosis is made, the better it is for both patient and physician. Though there are so many types of malaria, and though the symptoms in many cases are extremely vague, nevertheless, there is always present in the blood an organism which can be demonstrated by means of the microscope and thus allow one to differentiate malaria from all other diseases. This examination can be made as soon or as late as we desire after taking the specimen of blood, for the plasmodium malariæ can be seen either in the fresh or in the dried specimen. In hospitals it is more convenient to examine the fresh specimens; but in private practice I prefer to examine the dried.

The technic I employ is as follows: In my medical bag there are always cover-glasses and a large Hagedorn needle. The lower tip of the ear is cleansed with alcohol, which is allowed to dry thoroughly before the ear is punctured; the cover-glasses are washed with alcohol just before use, wiped dry, and protected from dust; absorbent cotton wrapped around the non-sulphur end of a match and soaked in alcohol gives a sufficient alcohol flame for sterilizing the needle; the puncture is made sufficiently deep to obtain the blood without having to squeeze the ear; the first drop is wiped off, and the second one caught on one of the cover-glasses; the two cover-glasses are placed in contact just long enough for the blood to spread, then drawn rapidly apart, and we thus have two spreads for examination. The spreads are now allowed to dry and then placed in a small tin box, there to remain until I am ready to stain them. In order to fix the blood before staining, about one teaspoonful of a 40-per-cent. solution of formaldehyde is placed in the bottom of an ordinary cheese-dish; the spreads of blood are placed in a small butter-plate; the plate is then set in the dish; the cover is placed over the dish, and the spreads are thus exposed to the formaldehyde gas for from fifteen to thirty minutes. The spreads are now stained first with a 1-per-cent. aqueous solution of eosin, washed, and finally stained for from one-half to one minute with a 1-per-cent. aqueous solution of methylene blue. Before mounting the spread on a slide it is best to look at it with a low lens of the microscope to see if it is stained blue enough, which can readily be ascertained by noticing the nuclei of the white corpuscles. After the spread has been mounted it is looked at with the 1-12 oil immersion lens. This method can readily be mastered by any one, and I do not think that any one will deny that the finding of the malarial parasite in the blood is very satisfactory; but, as many still claim that it is not at all necessary, I am going to report a few cases in which the diagnosis was made only through such a microscopical examination.

Case I.—Colored female, aged sixteen years. I delivered the patient of a full-term child on September 5, 1899. The puerperium was normal up to the ninth day, when she had a severe chill followed by fever and sweating. I saw the patient the next day, but she said nothing about having had a chill, and, as the temperature and pulse were normal, and as she seemed well in every respect, I told her I would not see her again for three days. On the thirteenth day I saw her and found that the temperature was 103° F.; pulse 115. She then told me of the chill on the ninth day; that she had had another on the eleventh day and had also had one several hours before my present visit. I ordered broken doses of calomel, put her on light diet, and took a specimen of her blood. The blood examination showed large tertian parasites. I put her on quinine and there was no repetition of the chill nor any further fever. I caught from the walls of the room, in test-tubes, ten or fifteen mosquitoes, two of which proved to be *Anopheles;* the rest were of the *Culex* variety.

Case II.—White female, aged twenty-eight years. The patient's youngest child was two months of age; breast-fed. Patient sent for me on June 25, 1900; she complained of her left breast being very painful and said that she had had a severe chill at 10.30 p. m. the day before. She also complained of severe pain in back, head, and lower extremities. Examination showed the left breast to be very painful on pressure; some superficial redness in upper, outer, quadrant, but there was no marked induration, nor was the breast at all nodular. Thinking the breast signs not sufficient to account for the symptoms, unless she had a submammary abscess with absorption of pus, I made a thorough examination. The lungs and heart were nega-

[1] Read at the annual meeting of the Virginia Medical Society, held at Charlottesville, October 24, 1900.

tive; the liver normal; the spleen was slightly enlarged and painful on pressure; the tongue was heavily coated; her bowels had not moved for two days. I took a specimen of blood for examination and put her on broken doses of calomel. The blood examination showed tertian parasites, and I can readily assure you that I was delighted to see them. She was put on quinine and all symptoms quickly disappeared.

Case III.—White female, aged nineteen years; schoolgirl. Since the middle of last June the patient had suffered from constant headache, anorexia and constipation. Patient had not been aware of having had any fever, and had had no chill nor chilly sensation. She went to see a physician, who treated her for torpidity of the liver, but there was no abatement of the symptoms. I saw patient at my office on July 23d. She complained of the symptoms mentioned; her tongue was heavily coated; she was quite pale, whereas she usually had a good color. Knowing that there was much malaria in the suburb where she lived, I took a specimen of her blood. Examination of the blood showed numerous large and small-sized tertian parasites. I put her on quinine and arsenious acid and told her to report to me in one week. At her next visit she said she felt much better, but that she still had the headache off and on. I continued the same treatment and asked her to let me see her again at the end of the week. On August 6th she came to see me, said she felt much improved, and wished to go to Baltimore on a visit. As she was still quite pale and had very little appetite, I took another specimen of her blood. Examination showed small tertian parasites, very few in number. I put her on iron, quinine and arsenic, and told her to go to Baltimore, but to keep up her medicine while there. She returned home the middle of September and told me that she never felt better in her life. She now has a good color and is attending to her studies at school.

Case IV.—This patient, a young white woman, had been suffering from headache, anorexia, and continued fever for two weeks. The temperature went up to 102° and 103° F. in the afternoon. The only signs were a coated tongue and a slightly enlarged spleen. A specimen of blood was taken and the examination showed tertian parasites. There were two sets of these parasites, one, large and pigmented, the other, small; there were also hyaline bodies. As the patient was very susceptible to quinine and had been advised by a physician never to take it, she was put on guaiaquin. The fever now became intermittent, but the continued use of guaiaquin, with the addition of arsenic, succeeded in removing the fever entirely. The fever returned in three weeks, and was again successfully treated by the same medication.

Case V.—Young colored man, farm laborer. The patient gave a history of having had "hot fevers" for several days, accompanied by severe headache. There had been no chill. The day before the present visit the patient was prostrated while working in the sun. Examination showed coated tongue, spleen slightly enlarged, bowels constipated. The temperature was 100° F. The specimen of blood showed small, intracorpuscular, ring-formed parasites. The patient was immediately sent to a hospital and broken doses of calomel ordered. The fever rose to 105° F. that afternoon. Quinine was administered and the fever disappeared in three days. The patient left the hospital in a short time, returned to work, but did not keep up the treatment as ordered. The fever returned in three weeks; he was put on quinine for a long period, and he never had any return of symptoms.[1]

Case VI.—White male, aged four and one-half years. The patient has been delicate since three months of age. Was nursed only seven weeks and then given condensed milk. During his second summer he had a severe case of cerebrospinal meningitis. I saw the child for the first time last May, when he was undergoing a severe attack of pertussis. On June 1st the pertussis became complicated with an attack of acute colitis, which persisted, with quite severe symptoms, until June 30th. I was called to see him in August. The history given was that he had had fever every night for the past week; was listless and would eat nothing; no history of vomiting, chill or chilly sensation. On examination the spleen was found to be enlarged; nothing abnormal was found in chest; tongue was coated and bowels constipated. I put him on calomel and took a specimen of blood. Examination showed small-sized tertian parasites. I also examined his urine, which proved negative. Put patient on quinine and all symptoms readily disappeared.

Case VII. — White female, aged thirteen months; breast-fed. I was called to see this child on September 27, 1900. The father had just recovered from an attack of malaria. The mother said that the child had had diarrhea for the past four days, from eight to nine stools daily, green in color; that the child had fever every night; was very restless and fretful and would nurse only a few minutes at a time. Examination showed a well-nourished child with six teeth; no rosary; chest, negative; spleen, enlarged; no fever; coated tongue; there was no history of vomiting. I ordered calomel in broken doses; ordered nothing but barley-water for thirty-six hours and took a specimen of blood. Examination of blood showed large-sized tertian parasites. I put the child on 2½ grains of quinine, four times a day, for three days; then 2½ grains twice a day, for the next three days, and kept up two grains once a day for ten days. All the symptoms readily disappeared and the baby continues well.

Case VIII.—White male, aged seven and one-half months; breast-fed. This case, in which I only examined the blood, is reported by me

[1] Class IV and V illustrate the value of blood examination in differentiating between malarial fever and typhoid fever.

through the courtesy of Dr. L. T. Royster, who attended the child. Negative family history; child convalescing from pertussis; paroxysms still occurred several times each day. The present illness began April 18, 1900. The child was seen for the first time on April 19th. Examination showed a well-developed and well-nourished child, but who was rather weak from the pertussis. Hygienic surroundings fair; countenance listless; eyes dull; skin dry; pulse 120; temperature 99° F.; respiration 25; tongue dry; anorexia; marked thirst; bowels in good condition; urine in sufficient quantity. Chest, small area of dulness at posterior left base; bronchovesicular breathing; numerous crepitant râles. Afternoon of same day, temperature 103° F.; pulse 160; respiration 48; almost entire lower lobe of left lung was consolidated; paroxysms of cough increased in frequency and force, and after each one there was marked Cheyne-Stokes breathing, which continued for half an hour. On the third and fifth day the temperature rose to 105° F., which was two degrees higher than on the second and fourth days. On the sixth day resolution commenced, the temperature falling to normal. On the afternoon of the seventh day the temperature rose to 105° F. A specimen of blood was now examined and it showed hyaline bodies. Quinine was administered and there was no further rise of temperature.

These are selected cases taken from the record kept of the microscopic examinations made by Dr. Charles R. Grandy and myself. I think they speak for themselves and show of what inestimable value the examination of the blood has been to me.

CLINICAL MEMORANDA.

IS RUBEOLA INFECTION ANTAGONISTIC TO PERTUSSIS INFECTION?[1]

By WILLIAM BYRD YOUNG, A.M., M.D.,
OF BON AIR, TENN.

The above question was forcibly presented to my mind last winter during a concurrent epidemic of measles and whooping-cough in my town. Not being an expert microscopist nor pathologist, I shall not attempt to present a research from this field, but will simply give my own experience, with some observations by a few of my colleagues in concurrent epidemics of measles and whooping-cough, in conjunction with the theories along this line of some recognized authorities.

During last winter and spring we had the severest epidemics of pertussis and measles in White County that I have ever witnessed. The whooping-cough made its appearance a few weeks previous to the outbreak of measles. Just about the time measles developed in a few of our families we had under our care, among other cases, four aggravated cases of pertussis in the height of the spasmodic stage. My associate, Dr. H. L. Fancher, and I made the remark one evening, while discussing the two epidemics, that as soon as the four patients mentioned contracted measles there would be four deaths. But to our great surprise not one of the four had a symptom of pertussis after the measles eruption was well developed, and all made an uneventful recovery from both diseases. These were as severe cases of pertussis as one ever sees. Each had almost all the unpleasant symptoms that are found in very aggravated cases during the spasmodic stage—the well-known paroxysms, with the deep purple, almost black, face, the peculiar "crowing" whoop, which in these cases could be heard two blocks away. The vomiting and epistaxis were both very marked. The children (aged from two to four years) would have from fifteen to twenty paroxysms per day. Two of the cases had hemorrhages from the mouth, which I thought came from the throat, with almost every paroxysm.

The question arose, what caused such a sudden cessation of so marked symptoms of the pertussis when it became complicated with measles? Did the germ or toxin of measles destroy or counteract the germ or toxin of the pertussis? Would the marked symptoms of the whooping-cough have ceased in the same way had it been complicated with scarlet fever or some other zymotic disease? Or was it simply a coincidence? I cannot call to mind a single instance in which a child contracted pertussis during, or for some time after, an attack of measles.

Dr. W. A. Hargis of Granville, Tennessee, in a paper on pertussis read before the Upper Cumberland Medical Society last May, reported several cases of whooping-cough during an epidemic of the disease in his town that contracted measles during the worst stage of the pertussis that never had a symptom of the latter disease after they were well broken out. Dr. S. G. Sullivan of Amande, Tennessee, in reporting to the White County Medical Society, May 10, 1900, a concurrent epidemic of measles and pertussis in his neighborhood during the previous winter, spoke of the singularity of the marked cessation of all symptoms of pertussis as soon as the measles rash made its appearance.

It should not be thought incredible that the infection of measles antagonizes the infection of pertussis. There are many instances in which one disease modifies very materially and often eradicates another disease that has previously affected the body. For instance, the members of this Society have all seen old chronic ulcers of the leg, or even on other parts of the body, entirely disappear after the patient had a severe attack of some lingering malady, such as typhoid fever. Dr. A. R. Robinson, Professor of Dermatology in the New York Polyclinic, in a paper read before the Canadian Medical Association in August, 1899, reports a case of cancer of the breast that

[1]Read before the White County (Tenn.) Medical Society, Nov. 8, 1900.

entirely disappeared and never returned after the patient recovered from an attack of typhoid fever.

We have all noticed patients, whom we might call chronic consumptives, who expectorate freely mucopurulent sputa every day of their lives, who, when they contract acute lober pneumonia frequently have a cessation of thick pus expectoration. A few months ago I was called in consultation with Dr. A. F. Richards of Sparta, Tennessee, to see a woman suffering from an attack of acute lobar pneumonia who had had chronic pulmonary tuberculosis for several years and up to the time of the attack of pneumonia was freely throwing off from the lungs a mucopurulent sputum. After the initial chill of the pneumonia the characteristic tuberculous expectorating ceased. Dr. Richards and I were at a loss to account for this, unless the pneumococci in some way have an unfavorable effect on the activity of the tubercle bacilli or mixed infection that accompanies phthisis.

Those of the Society who have been keeping up with the latest developments in regard to the treatment of cancer have observed the remarkable results that Dr. W. B. Coley of New York has reported in the treatment of cancer by the use of the mixed toxins of erysipelas and the bacillus prodigiosus, injected, when possible, directly into the cancerous growth. Dr. Coley read a paper before the New York Academy of Medicine, March 1, 1900, in which he gives the following results of his treatment of a cancer by the mixed toxins. (See Medical News, Vol. 76, p. 57.) "Of the total number of cases treated, eighty-five were round-cell sarcoma, twenty-one spindle-cell, and nine melanotic sarcoma. Of the round-cell variety forty, or less than half, showed more or less improvement and in three the treatment had been successful. On the other hand, of the twenty-one spindle-cell sarcoma, ten had disappeared entirely, and all the remainder had shown marked improvement." Coley cannot account for the actions of the toxins only on the theory of the parasitic origin of cancer.

Other reports from other experimenters could be cited to show that the toxins of erysipelas and of the bacillus prodigiosus affect and, in a large percentage of cancer cases treated by this method, destroy the parasites and neutralize the toxins of the cancer.

When we see how the mixed toxins of these germs antagonize, so to speak, the deadly poison or parasites of a heretofore incurable disease, is it unreasonable to suppose the germs or toxins generated by the attack of measles did not destroy the parasites or neutralize the toxins of pertussis in the concurrent epidemic referred to, especially when we know that the infection of the two diseases begins its work on the same mucous membrane, that is, of the nasal cavities.

Dr. Charles T. McClintock of Detroit, in a paper read before the Mississippi Valley Medical Association, a few years ago, on the subject of "Enzymes and Immunity," speaking of the influence one germ may have over another germ, says, "That one germ or its products can aid or hinder the work of other germs has long been known, and it has been the dream of many workers that we would ultimately fight disease germs with other germs or their products. It appears as if this dream is about to be fulfilled." Dr. McClintock further says that "Löew and Emmerich report that two cubic centimeters of a solution of an enzyme obtained from the bacillus of green pus will kill two and a half million virulent anthrax germs in five minutes. According to these authors this enzyme rapidly destroys large numbers of the germs of typhoid, diphtheria, plague, etc." Here we have, again, one germ or its products destroying the germ of other diseases.

We would, therefore, conclude that it would be nothing strange or improbable to find that the germs of measles or their products will destroy or neutralize the germs or toxins of pertussis. To say the least, from a careful study of the subject, from the observations of other physicians, and from my own personal experience, it is difficult to believe that the cases above referred to were merely incidental.

COMPLETE TRANSPOSITION OF THE VISCERA.[1]

By GEORGE W. WEBSTER, M.D.,

of Chicago;

Professor of Physical Diagnosis in the Northwestern University Medical School.

The case which I have the pleasure of presenting is one of complete transposition of the viscera, including the lungs. I believe the lungs are transposed for the following reasons: On account of its size and the angle at which the right bronchus is given off, and possibly for other reasons, the percussion sound on the right side in the infraclavicular space is slightly higher in pitch. In the same situation, the normal respiratory murmur is slightly harsher in quality and raised in pitch and the normal vocal resonance is increased. In this case the normal disparity is reversed, seeming to warrant the conclusion that the lungs are transposed.

Congenital anomalies and malformations of the heart have excited the interest of physicians for nearly a hundred years. Peacock, in 1855, was the first to issue a systemic treatise on the subject, attempting to reduce the different forms of irregular development to scientific arrangement, being guided only partly by the period at which the development of the organ becomes arrested or perverted.

In 1875, Rokitansky of Vienna published a monograph in which he insisted on the importance of studying the anomalies in connection with the different stages of development. Recently Féré has demonstrated that marked modifications in development may be produced in the chick, by injecting pathogenic germs and toxins into eggs undergoing incubation. These experiments show that agents which produce disease during

[1] Read before the Chicago Society of Internal Medicine, November 27, 1900.

extra-uterine life and later during intra-uterine existence give rise to malformations in the earlier phases of existence.

Ballantyne puts it thus: "The same causes are in action in both periods, but when influencing an embryo so far developed as to have specialized organs, the result is disease. When, on the other hand, influencing an embryo in which such specialization has not been carried on to the same extent, the result is a malformation. In the one case the results are pathological; in the other, teratological."

We are probably justified, therefore, in concluding that the causes of congenital diseases and malformations are similar and may be identical. Among internal displacements, that of transposition of the viscera is perhaps the commonest. Dextrocardia may be present without transposition of the viscera, but such cases are rare.

Two hypotheses have been proposed in explanation of this anomaly. Dr. Frazier suggests that the transposition may be due to the subject having been one of twins which were developed from a single ovum and in which dichotomy was complete. Von Baer has found that in a few instances the embryo lies with its left side directed toward the yolk, whereas the right side is normally in this position.

MEDICAL PROGRESS.

Fractures of the Leg.—Better than the time-honored exact reposition under ether with plaster cast, the extension with weights or the constant elastic traction methods is the employment of the following simple apparatus, says N. KAEFER (*Centralbl. f. Chir.*, Jan. 5, 1900), which he has lately brought out. Its parts are two flat, very strong, roughly-corrugated wrought iron braces about 10 c. m. long by 1.8 c. m. wide, slightly elbowed at one end where plays a screw. This screw is turned out of a hexagonal piece of steel so as to have a right and left thread, with a hexagonal piece between them to serve as a nut, for the approximation or separation of the braces. The application of the device is briefly, a carefully and densely applied plaster splint is cut through circularly so as to leave an upper and lower half separated by an interval of perhaps 3 c. m. Over this space is placed the center of the screw and the braces are rapidly fastened to the splint by many layers of plaster bandage. When all is dry the screw is turned so as to part or draw the half-splints together as indicated. The braces are placed laterally, are so strong that one alone is needed. They have the advantage of being adjustable from day to day.

Pharyngeal Adenoids.—The importance of recognizing the presence of pharyngeal adenoids in the young has certainly never been thoroughly appreciated by the ordinary general practitioner. When we learn that they are responsible for more than one-half of the pathological conditions met with in the ear and that most cases of deaf-mutism are not really congenital, but acquired and due to adenoid vegetations during infancy, the need of more careful investigations into the causes of nasopharyngeal obstructions is readily seen. P. D. KERRISON (*N. Y. Med. Jour.*, Feb. 2, 1901 urges that it is not those cases which present the typical symptoms that are usually neglected, for the diagnosis is then clear, but when only partial obstruction occurs and the symptoms are those of frequent rhinitis, pharyngitis, tracheitis, bronchitis, and mouth-breathing, at least during a part of the day, the underlying cause is liable to be overlooked until the child's development is seriously interfered with or a complication occurs. Careful examinations have shown that the adenoids frequently contain tubercle bacilli, and diphtheria is especially virulent in children with vegetations. The ear complications are, however, the more common serious results secondary to these growths. Lesions of the conducting portion of the auditory apparatus first appear, such as tubal catarrh, otitis media and mastoiditis, but the internal ear may also be affected. Adenoids usually atrophy at puberty, but it is not very uncommon to see people of adult or even middle life suffering from the effects of these growths. Thorough removal is the only rational treatment. A general anesthetic is usually advisable and the adenoids grasped and removed by forceps specially constructed. The site should then be curetted with a Gottstein curette to remove every shred, for adenoids tend to recur if any part is left.

Arsenical Dermatitis.—This condition usually results from a prolonged use of arsenic under a physician's direction or to occupation exposure. An unique case is reported by A. H. OHMANN DUMESNIL (*N. Y. Med. Jour.*, Feb. 2, 1901) in which a woman took over a dram of "Rough on Rats" with suicidal intent. Her stomach was washed out twice within a few hours. On the second day she presented a vesicular and pustular eruption on the hips, face and nose and a small patch of confluent vesicles on either buttock. She complained of a burning sensation and of some itching. The appearance of the eruption after a single toxic dose and the location of the lesion were considered unusual.

Tuberculin Test.—After a wide experience in the use of this test for diagnostic purposes in cases of suspected tuberculosis, J. M. ANDERS (*Internat. Med. Mag.*, Jan., 1901) concludes that it is a very valuable aid. Out of 3638 cases a reaction was obtained in 2185. The number that were clinically doubtful at the time of the injection was 1468 and 70 per cent. of these reacted. It is advised, however, that it should be used in medium-sized doses and only in those instances in which the diagnosis is very doubtful or otherwise impossible.

Oxygen Treatment of Uric-Acid Lesions.—The presence of an excess of uric acid or its compounds in the blood is supposed to be due to a diminished power of oxidation on the part of the organism, and either a diminution in the proteid food or an increase in the oxygenation process may be induced to counteract the condition. A. C. CROFTAN (*Internat. Med. Mag.*, Jan., 1901) believes that the uric acid is non-toxic, but that the alloxuric bases which are closely allied are very poisonous and depend upon the oxidation power. The metabolic processes resulting in chemical oxidation occurs not only in the blood as it passes through the lungs, but also in all the tissue cells. To raise the oxygenation in the blood one may improve the quality of the inspired air or the number and activity of the red blood-cells. Inhalations of oxygen give uniformly good results, especially striking in functional disorders. The gas is procured in cylinders of 50 to 200 gallons at from four to seven cents per gallon. Rubber-bags, holding about five gallons, are filled with the gas which is inhaled by long deep breaths. The séance lasts about five minutes and is repeated daily at first. With this mode of treatment, diet and climate are usually combined if possible.

Skin in Scarlet Fever.—The rash is made up of small puncta, writes J. F. SCHAMBERG (*Proceedings Phil. Path. Soc.*, Jan., 1901), surrounded by erythematous areolæ, which may coalesce or leave normal areas of skin between. The punctæ are often about the hair-follicles, or there may be a general "goose-flesh" papulation. Minute discrete vesicles are common, and sometimes become so large and abundant as to deceive the physician. The area between the punctæ represents an acute dermatitis, the goose-flesh results from an infiltration in and about the hair-follicles, and the vesicles originate in the follicles or in the deeper layers of the *rete*, contain a turbid leucocytic fluid, and dry up to form powdery scales on the surface. The punctæ are either infiltrated hair-follicles or dilated blood-vessels with intense perivascular exudation.

Congenital Stenosis of the Pylorus in Sucklings.—In a recent monograph GILLOT (*Thèse de Paris*, 1900) has gone over the literature of the subject and reaches some interesting conclusions, regarding this condition, based on critical consideration of the thirty-three cases which he was able to gather. Even some of these cases, the author finds, are not entirely reliable. In the first the affection is admittedly very rare, and only diagnosticated on the post-mortem-table in the majority of cases. Nevertheless Gillot believes that closer study of the symptomatology will enable and facilitate diagnosis in the future. The vomiting, constipation, and rapid wasting, notwithstanding irreproachable feeding, are considered the cardinal symptoms upon which a diagnosis may be reached. The condition is considered under two heads, that relating to organic stricture of the pylorus and that merely due to spasmodic contraction of the pyloric ring. All of the cases which have been treated medicinally have succumbed; therefore, the author urges gastro-enterostomy as a promising and logical treatment.

Perineorrhaphy.—H. FRITSCH (*Centralbl. f. Gynak.*, Jan. 12, 1900) makes the following points regarding this operation. Two principals are vital: (1) Remove no tissue if possible, sacrifice nothing while in the old sense "freshening" the wound, but rather divide so as to approximate the proper parts each to each; (2) unite with accuracy the torn ends of the sphincter. The first-named goal is easy to attain in recent cases, when the freshly-lacerated tissue can still be brought together and is in itself scar-free; but when the tear has existed some time, and especially when one or more operative attempts at repair have failed, the amount of cicatricial tissue is so considerable that the work becomes at once difficult. The vagina and rectum are often adherent and the external sphincter reduced to a functionless semi-circular muscular band. The two viscera must at first be freed, each from the other, then the rectum sutured, next the intervening connective tissue and, finally, the vagina with the skin. Often the sphincter will be found so contracted that the little finger can scarcely be passed into it, and it forms a barrier for gas, mucus and feces. These collect in the ampullae recti above, also contracted by disuse, and soon force the wound open again completely or partially or, invading the new perineum, cause fistula. For such cases at the time of the operation a rubber tube wrapped with gauze may be inserted through the anus to act as a vent. Simon has suggested and the writer has tried division of the sphincter in the middle line posteriorly toward the sacrum as a preliminary step in the operation, but results in a painful granulating wound. Hence the author now divides the sphincter after the plastic work is completed subcutaneously. The results show that function returns as well as it does after fistula-in-ano operations. For the deep sutures non-absorbable material is recommended.

Complete and Immediate Withdrawal of Drug in a Cocaine Habitué.—GEORGE WILLIAM NORRIS (*Phila. Med. Jour.*, Feb. 9, 1901) reports the case of a dentist, aged thirty years, who had been using cocaine for ten months. At first he had used the drug locally for hemorrhoids, but after the cessation of the pain he still continued to use the drug by hypodermatic injection in gradually-increasing doses, until his average was sixteen grains a day. Insomnia was constant unless he took cocaine in small repeated doses. He had hallucinations of hearing, and finally, becoming alarmed at his condition, sought medical advice. The cocaine was completely and immediately withdrawn. He was given strychnine sulphate, grain $^1/_{30}$, every fourth hour, and sulfonal,

grains 20, repeated in two hours. During the first night the patient slept fairly well, and on the second he required no hypnotic whatever. He felt well and had no craving for the drug. The interesting points are: (1) That sudden and entire withdrawal of the cocaine after long-continued use in large doses required no more active therapeutic substitution without producing physical effect; (2) that the patient after the first twelve hours had little craving, but remained quietly in bed without suffering any of the agonies usually experienced on the discontinuance of a long-established drug-habit. The writer also tabulates the following facts concerning acute and chronic cocaine intoxication: (1) Cocainism is the most insidious of all drug-habits. The use of the drug being unaccompanied by disagreeable after-effects, the vice is readily and rapidly established; (2) cocainism is occasionally acquired by the local use of the drug in diseases of the nose and throat, teeth, etc., but more often as a substitute for opium or alcohol; (3) cocaine is eventually tolerated by the system in huge doses; (4) a relatively large number of habitués are found in the medical and dental professions; (5) the continued indulgence in cocaine invariably, and usually soon, leads to marasmus, with mental, moral, and nervous degeneration; (6) the smallest fatal dose on record is $^1/_3$ grain hypodermatically; (7) while many cases of acute intoxication are being continually reported, there are relatively few fatal cases, the majority of such being the result of large doses injected into the urethra and bladder; (8) the amount of cocaine sold yearly is rapidly increasing, and its self-prescribed use among the laity and lower classes becoming proportionately more frequent.

Sterilization of Catheters.—M. W. Herman (*Centralbl. f. Chir.*, Jan. 19, 1901) has found that silk catheters may be boiled without damage in a solution of ammonium sulphate, precisely after the method of Elsberg for boiling catgut. The smoothness of their inner and outer coats, their elasticity and their general wearing qualities are not affected by boiling continuously or interruptedly. The catheters may be taken directly out of the solution and used, without apparent damage to the urethra by chemical irritation. The author has found the same method adequate for sterilizing Nélaton's catheters, elastic sounds, ball-sounds, filiform bougies and similar instruments.

Syphilis and Exophthalmic Goiter.—R. Abrahams (*Phila. Med. Jour.*, Feb. 9, 1901) reports in detail the cases of three women in each of whom syphilitic symptoms were followed by undoubted symptoms of exophthalmic goiter. All symptoms, both of the syphilis and of the exophthalmic goiter, disappeared as the result of vigorous antisyphilitic treatment. The writer believes that syphilis was the etiological factor in these cases of Basedow's disease, and from these cases summarizes the following conclusions: (1) The occurrence of exophthalmic goiter in three undoubted syphilitics cannot be regarded as either accident or coincident; (2) the old dictum which relegates the origin of exophthalmic goiter to a perturbance or disturbance in the cervical sympathetic system should receive attention only after the existence of syphilis, present or past, be absolutely excluded; (3) those cases which yield to mercury or the iodides should be favorably looked upon as being of syphilitic origin; (4) cases in which all the orthodox remedies fail should be put to the test of specific treatment; (5) cases which are characterized by gangrene of the extremities, various pigmentation of the skin, nocturnal headaches, or other suspicious luetic symptoms, should receive the benefit of specific remedies.

Peaceful Narcosis.—For the acquiring of peaceful and regular breathing under narcosis C. Hofmann (*Centralbl. f. Chir.*, Jan. 19, 1901) says the following points must be observed: It is an error to confide narcosis to an inexperienced person. A competent assistant is the only one who should have this in charge, whether chloroform or ether be used the drop-by-drop method upon an Esmarch inhaler will be found best, and, by beginning very slowly and evenly, almost all the unfavorable signs will disappear. A small dose of morphine about an hour before the narcosis is advisable.

Post-operative Hernia.—After reporting in detail six cases of post-operative hernia, illustrating the conditions found in this class of hernia and the steps of the operation for their cure, and discussing the conditions which predispose to the development of post-operative hernia and the measures which should be used to minimize these factors at the time of the operation, Irving S. Haynes (*Phila. Med. Jour.*, Feb. 9, 1901) gives a few practical directions for the radical or operative treatment of this condition: (1) Make the incisions on each side of the old scar in healthy skin, even though a large segment must be excised; (2) look for and recognize the various muscular or fascial planes at a distance from their involvement in the scar, then incise the layer near the scar, but in normal tissue; (3) divide the peritoneum far enough from the cicatrix, so that its normal features are easily recognized; (4) severe adhesions of the hernial sac to viscera or omentum, between ligatures when necessary; (5) an omental stump is to be covered up by rolling it into the omentum and keeping it there by a running suture of free catgut; bare surfaces of intestine should be covered by bringing the peritoneal coats together. Subsequent adhesions are thus prevented; (6) close the wound with chromic catgut. It is taken for granted that all oozing has been arrested. The patient should rest in bed for three weeks afterward, if possible.

Tracheotomy for Foreign Body.—H. Milton (*Lancet*, Jan. 26, 1900) narrates the history of a case of foreign body in the bronchus removed by intrathoracic tracheotomy, as follows: The forty-year-old patient had undergone trache-

otomy of a syphilitic cicatricial stenosis of the larynx some years before his readmission. The curved silver tube had loosened gradually from the collar and then fallen into the trachea. When admitted the man did not show urgent symptoms. Attempts to reach the tube through the tracheotomy opening failed. The signs of fetid bronchitis developed and operation was determined on. Chloroform anesthesia was adopted. The muscles and tissues at the presternal notch were freed and, with the finger, protecting the great vessels, the strenum was divided from end to end and its halves separated for two inches. By retracting the great vessels and drawing the trachea upward, it was possible to open it just over the bifurcation. The tube was then withdrawn. The septic condition caused a bronchitis, then pneumonia and abscess of the anterior mediastinum. Death followed. The author thinks a subperiosteal ablation of the manubrium sterni would have afforded a better drainage, although the sepsis already present was the fatal element in this case, which is his second.

Gastric Perforation.—Pain in the thoracic parietes situated in the scapular, subscapular or interscapular regions, observes J. L. Faure (*Semaine Médicale*, Jan. 23, 1900), is a very frequent accompaniment of intra-abdominal and subdiaphragmatic lesion. The presence of this pain, though itself of the type of *referred pain*, is very important and suggests the abdominal contents as the true underlying source. It is consequently urgently necessary at the onset of other signs of visceral disease below the diaphragm to ascertain whether these high-seated pains were long antecedent to, immediately coincident with or distinctly subsequent upon the other symptoms. The writer says that the most frequent process causing this pain is a perforation of a gastric ulcer, which seems prone to refer its pain to the interscapular region, near the midline. Hence in the presence of it, concomitant or subsequent to other signs, exploration of the stomach through the epigastrium is at once indicated.

THERAPEUTIC HINTS.

Cerebrospinal Meningitis.—Depletion is to be condemned, says F. B. Maynard (*Albany Med. Annals*, Nov., 1900), as the homogenetic function of the body is largely suspended. The cold pack is most valuable, the patient being stripped and placed in a twice-folded, wet sheet, with his head on an ice-bag, two-thirds full of water and crushed ice. The constipation yields to calomel. Potassium bromide is the best routine drug, with potassium iodide to promote absorption of the exudate, and alcohol and morphine as indicated. Lumbar puncture is of no therapeutic value, the antistreptococcus serum may prevent the exudation, becoming purulent, and Credé ointment may prove of similar value. The latter, however, requires twenty minutes' friction to insure absorption, and this would not be possible on account of the intense hyperesthesia caused by the disease.

Exercise in Tuberculosis.—Parker Murphy (*Albany Med. Annals*, Nov., 1900) instructs his patients to breathe deeply, and, when the fever declines, to perform extension movements, slowly raising the arms to the horizontal, then over the head until the hands meet, at the same time slowly and deeply inspiring and expiring. All the exercises to increase the lung cavity must be coincident with deep breathing. The importance of expanding and revivifying as soon as possible a lung the nutrition of which is depressed can hardly be overestimated.

Tuberculous Spondylitis.—Forcible correction of deformity, writes A. C. Wiener (*Medicine*, Feb., 1901), is indicated only in recent cases. The reflex spasm yields soonest to extension in bed, then the patient can be gotten up and with an extension apparatus can be out-of-doors. A little weight at night relieves pain and favors sleep. In paraplegia, laminectomy is indicated only in those rare cases of sudden development of the kyphos with paralysis. The gravitation abscess is best not opened and drained, as it forms a persistent sinus, but about once or twice a week the fluid may be withdrawn by a trocar, and carbolic acid, from 6 to 15 drops of a 95-per-cent. solution slowly injected.

Nephritis.—To encourage diaphoresis in acute nephritis John Perrier (*Cleveland Med. Gaz.*, Feb., 1901) puts patients to bed between woollen blankets, and gives hot drinks of lithia, lemonade or plain water; if there is fever add liq. ammon. acetat. and aconite or veratrum viride. Make diet of bland, nutritious liquids, and open bowels with saline cathartics in hot concentrated solution. In severe cases the hot-air bath, with a lamp and tin pipe arranged to make hot air pass beneath the bedclothing, may be of benefit. The nausea and vomiting usually respond to fluid diet and frequent, small doses of hot water, carbonated waters, cracked ice, bismuth and morphine, or to sinapisms over the epigastrium. For suppression of urine apply linseed-meal poultices containing mustard, to loins every four hours. Where uremia is threatened the hot pack, and for convulsions, chloroform, are indicated, and if the heart is full and strong pilocarpine is good. When all other means fail, the subcutaneous injection of normal salt solution, about 1 liter (one quart) every 6 to 12 hours, is most valuable, or it may be given by high enema. The most effective cathartics in uremia are elaterium or croton oil in small dose frequently repeated, and combined with calomel. As improvement begins, give farinaceous foods and a tonic of quinine or other bitter, with iron for anemia. Avoid meats and alcoholic stimulants.

SATURDAY, MARCH 2, 1901.

WHY IS THERE NO DOCTOR?

Vice and its henchman are in deep waters and the wave of reform threatens to sweep many a well-anchored institution in this city. We have hitherto had amateur reforms, most excellent and virtuous, by self-appointed committees of one, by churches and by moralists, that have simply raked the seeds of iniquity out of their hot-beds and sown them a little more widely over the whole city. But we have hopes that the Committee of Fifteen will accomplish something more by its methods than inciting the organization of specially sensational raids to fill yellow journalism's columns.

There is but one trace of the amateur in the Committee's make-up, in that it dispenses with the services of one of the most important classes of citizen, almost the only one that can contribute a scientific element to some of the most intricate phases of the investigation, namely, the physician. There is no expert medical man on the Committee, and if the reform, from the aspect of the social question, at least, is to be anything more fundamental than the periodic outburst of righteous indignation in the past, it must go deeper and be placed on a physically scientific as well as moral basis. We therefore commend the action of the New York County Medical Society in the proposed appointment of a committee to investigate the medical features of the social evil of this city.

It is comparatively simple to arouse public sentiment; but public sentiment is a drowsy watcher and quickly falls asleep. It is easy to chase off the birds of prey; but the vultures that hover over the city's sins are keen-eyed and hungry, and experience has shown that after each clamorous reform they have stealthily and silently come back to their pickings in greater number than before.

Many moralists seem to be content when they have closed the gambling-houses and places of prostitution, and made laws to annoy their proprietors; but reform, scientific reform must go deeper. The question comes back to one of a physiological and psychological basis which a man with a wide medical experience can best understand.

Perhaps the Committee of Fifteen have felt that the presence of a physician would only dampen their ardor by forcing them to a pessimistic realization of the situation. If that is the reason for their having no doctor among their number, they cannot have analyzed the social question very carefully.
